In recent electron-positron angular correlation measurements the observed significant enhancements relative to the internal pair creation at large angles was interpreted as indication of the creation of $J^\pi = 1^+$ boson called X17 particle. In this paper it is brought up that such enhancements can be generated by higher order processes. It is found that nuclear transitions, the transition energy of which is significantly lower than the whole transition energy, can cause peaked angle dependence in electron-positron angular correlation.

Keywords: anomalous internal pair production, nuclear decay

Introduction.—The anomalies in the spectra of emitted positrons observed in heavy-ion collisions at GSI (Darmstadt) in the 1980's [1] - [4] inspired experimentalists after the suggestions of [5], [6] to search for traces of a short-lived neutral particle [7], [8] produced in nuclear decays. The observed significant deviations from internal pair conversion [9], [10] sustained the interest [11], [12] searching for a light neutral boson [13] which is called X17-boson. Interpreting recent experiments, it was stated that 'to the best of our knowledge, the observed anomaly can not have a nuclear physics related origin' [14]. In this paper the anomaly is explained within nuclear physics.

In the experiments [14], [15] and [16] the decay of excited nuclear states through internal electron (e^-) - positron (e^+) pair creation (IPC) was studied. The examined process was assumed to take place in two successive steps. First, the excited states of nuclei were prepared in resonant (p,γ) reactions. Pair creation is expected after it in a second order electromagnetic scattering process [17] - [20]. The Θ dependence of the IPC yield fulfilling the $E_- + E_+ = \Delta$ constraint was investigated [14], [15] where Θ is the angle between the momenta $\mathbf{p}_- = \hbar\mathbf{k}_-$ and $\mathbf{p}_+ = \hbar\mathbf{k}_+$ of the emitted e^- and e^+ particles. E_- , E_+ and \mathbf{k}_- , \mathbf{k}_+ are the energies and the wave vectors of e^- and e^+ , respectively. Δ is the energy of the resonantly excited transition and \hbar is the reduced Planck-constant. Extra events, which were said to be unexplainable with IPC, were found.

It was supposed that parallel with the usual e^-e^+ pair creation, which is the usual IPC, the decay of the state may also take place by emitting a hypothetical X17-boson that also decays by e^-e^+ pair creation having characteristic Θ dependence. If these extra e^-e^+ events originate from the decay of the X17 boson then its rest mass can be determined with the aid of the given Θ dependence of the peaking anomaly appearing around a definite large Θ angle. Two different experiments [14], [15] resulted rest masses identical within experimental error with high confidence level [16].

However, in the analysis of experiments observing anomalous pair production the possible effect of higher order processes was not taken into account. Evaluations are based on the assumption that the populating $p + {}^A_Z X \rightarrow {}^{A+1}_{Z+1} Y + \gamma$ capture reaction and the IPC process take place in two succeeding steps. But higher order coupled reactions, like the ones to be discussed here and which are one joined processes contrary to the former two step one, may also happen. In the higher order processes the creation of the ${}^{A+1}_{Z+1} Y$ nucleus and the e^-e^+ pair are governed by strong and electromagnetic interactions. It is thought that the anomaly arises if the observed e^-e^+ coincidences are examined in the light of the two step process only.

Statement of this Letter.—The higher order processes, in what strong and electromagnetic interactions are coupled and govern jointly the system from the definite initial state to the definite final one, are investigated. It is shown that they can produce local maximum around a definite, sometimes large Θ value in the Θ dependence of the e^-e^+ pair creation yield. Consequently, they may be, at least partly, responsible for the observed anomalous e^-e^+ pair creation events.

General considerations.—The usual IPC process can be described with the interaction $U_{EM}^{(2)}$, the matrix element $\langle \nu | U_{EM}^{(2)} | \mu \rangle \equiv U_{EM,\nu\mu}^{(2)}$ of which between states $|\mu\rangle$ and $|\nu\rangle$ contains the Green function $exp(iK_{\alpha\beta}R)/R$ where $R = |\mathbf{r}_e - \mathbf{r}_N|$ [19], [20]. Here \mathbf{r}_e and \mathbf{r}_N are the electron/positron and nuclear coordinates and $K_{\alpha\beta} = |\Delta E_{\alpha\beta}|/(\hbar c)$ is the transition wavenumber with $\Delta E_{\alpha\beta}$ the change in the energy of nuclear transition $\alpha\beta$ and c the velocity of light in vacuum.

Using plane wave $exp(i\mathbf{q}\mathbf{r}_e)$ for the coordinate dependent parts of the states of the electron-positron pair, and expanding $exp(iK_{\alpha\beta}R)/R$ and the plane wave in terms of spherical harmonics [21]

$$U_{EM,\nu\mu}^{(2)} \sim \frac{1}{K_{\alpha\beta} (K_{\alpha\beta}^2 - q^2)} \left(\frac{q}{K_{\alpha\beta}} \right)^L \quad (1)$$

where $q^2 = \mathbf{q}^2$ with $\mathbf{q} = \mathbf{k}_+ + \mathbf{k}_-$ and L is the multiplicity of the nuclear transition. This characteristics of $U_{EM,\nu\mu}^{(2)}$, which gives the basis of the Θ dependence of the yield of e^-e^+ pair creation [17] - [19], may help to understand the main features of the Θ dependence.

In the case of usual IPC, i.e., if $\hbar c K_{\alpha\beta} = E_- + E_+ = \Delta = \hbar c \delta$, in the denominator of (1) the factor $K_{\alpha\beta}^2 - q^2 = \delta^2 - [k_-^2 + k_+^2 + 2k_-k_+ \cos(\Theta)]$ increases with increasing Θ for fixed magnitudes k_- and k_+ of the electron and positron wave vectors. But in higher order processes $|\Delta E_{\alpha\beta}| \rightarrow 0$, i.e., $K_{\alpha\beta} \rightarrow 0$ can also happen. In this event $K_{\alpha\beta}^2 - q^2 \rightarrow -q^2$ and $q^2 = k_-^2 + k_+^2 + 2k_-k_+ \cos(\Theta)$ decreases with increasing Θ . As a result, the magnitude of the corresponding matrix-elements decrease in the usual $|\Delta E_{\alpha\beta}| = E_- + E_+$ case and increase in the $|\Delta E_{\alpha\beta}| \rightarrow 0$ case with increasing Θ . In the later case, extra e^-e^+ coincidences are expected when $\Theta \rightarrow 180^\circ$.

However, in higher order processes nuclear transitions of $|\Delta E_{\alpha\beta}| < \Delta$ can happen. In these cases the $K_{\alpha\beta}^2 - q^2 = 0$ condition determines the angles

$$\Theta = \arccos \left[\frac{K_{\alpha\beta}^2 - (k_-^2 + k_+^2)}{2k_-k_+} \right] \quad (2)$$

at which singularities appear. For a nuclear transition of given $\hbar c K_{\alpha\beta} < \Delta$ the minimum angle Θ_m of a possible singularity arises if $k_- = k_+$. The angles Θ of singularities belonging to the cases $k_- \neq k_+$ fulfill the condition $\Theta > \Theta_m$. The linked k_- and k_+ values are determined by the $E_- + E_+ = \Delta$ condition. The singularities are moderated into peaks due to the width $\Gamma_{\alpha\beta} = \hbar c \gamma_{\alpha\beta}$ of the nuclear transition $\alpha\beta$. These peaks may appear in the transition probability per unit time W_{fi} of the 3rd or higher order processes too and they are thought to be responsible for the observed peaked anomalies in the measured coincident e^-e^+ events. The width $\gamma_{\alpha\beta}$ causes the modification of $K_{\alpha\beta}$ as $K_{\alpha\beta} \rightarrow K_{\alpha\beta} - i\gamma_{\alpha\beta}/2$ in (1). This modification can also be used in the results of [17]-[19].

Transition probability per unit time, W_{fi} .—The transition probability per unit time W_{fi} can be expressed with the aid of the transition-matrix (T -matrix) element T_{fi} as

$$W_{\text{fi}} = \frac{2\pi}{\hbar} \sum_f \int \int |T_{\text{fi}}|^2 \delta(E) \frac{V^2}{(2\pi)^6} d\mathbf{k}_+ d\mathbf{k}_- \quad (3)$$

where $\delta(E) = \delta(E_+ + E_- + E_f - \Delta)$, V is the volume of normalization and the sum is made over those final states of energy E_f which may contribute to e^-e^+ creation. T_{fi} may have many relevant terms, $T_{\text{fi}}^{(3)}$, $T_{\text{fi}}^{(4)}$, etc., which may be responsible for e^-e^+ creation with some of them for the observed anomalies. $T_{\text{fi}}^{(n)}$ is the term obtained in n th order of standard perturbation calculation [22]. The $T_{\text{fi}}^{(n)}$ terms can be expressed with the aid of $U_{EM}^{(2)}$ and V_{st} where V_{st} stands for the potential of strong interaction.

Although in a systematic overview the contribution by all terms must be taken into account we now focus on the terms which may be essential in producing extra e^-e^+ events of peaked Θ dependence.

Study of the T -matrix element.— Let us see first a process, the $T_{\text{fi}}^{(3)}$ of which can be obtained adapting the graphs given in [23] changing the interaction of particles 1 and 2 to strong interaction. In this case $T_{\text{fi}}^{(3)}$ itself has many terms. The slowly moving nucleus ${}_{Z+1}^{A+1}Y$ created by strong interaction and the initial free proton or the free target nucleus before entering strong interaction may emit e^-e^+ pairs [24]. In the corresponding three terms of $T_{\text{fi}}^{(3)}$ the $K_{\alpha\beta} \rightarrow 0$ approximation holds leading to $\exp(iK_{\alpha\beta}R)/R \rightarrow 1/R$. These terms have $1/[k_-^2 + k_+^2 + 2k_-k_+ \cos(\Theta)]$ like Θ dependence, which increases with increasing Θ . Their effect will not be discussed here.

The strong interaction, which is put in the graphs given by [23], can lead to an excited state $|n\rangle$ of energy $E_{n\nu} = \varepsilon_{n\nu} - i\Gamma_n/2$ where Γ_n is the width of the nuclear state $|n\rangle$ of energy distribution $\rho_{\varepsilon_{n\nu}} = [\Gamma_n/(2\pi)] [(\varepsilon_{n\nu} - \varepsilon_{n0})^2 + \Gamma_n^2/4]^{-1}$. Here ε_{n0} is the centre of the distribution. The energies $\varepsilon_{n\nu}$ and ε_{n0} are measured from the energy E_{f0} of the ground state of ${}_{Z+1}^{A+1}Y$.

In the case of ${}^8\text{Be}$ [14] two cases of resonant excitation were studied. These are suffixed with $l = 1, 2$ further on. The condition of resonance is determined by rest energies E_{i0} and E_{f0} of the initial and final nuclei, the centre ε_{r_l0} of the energy distribution of the state, which is tuned to resonance, and the centre ε_{0l} of the energy of the proton beam as $\varepsilon_{r_l0} = \Delta_0 + \varepsilon_{0l}$ with $\Delta_0 = E_{i0} - E_{f0}$. Now $n = r_l$ and $\Delta = \Delta_0 + \varepsilon_{0l}$. Applying the correspondence $\sum_\nu \rightarrow \int \rho_{\varepsilon_{r_l\nu}} d\varepsilon_{r_l\nu}$, the relevant T -matrix element can be written as

$$T_{\text{fi}}^{(3,r_l)} = U_{EM,fr_l}^{(2)} V_{st,r_l i} \frac{\Gamma_{r_l} - id_l}{(d_l^2 + \Gamma_{r_l}^2)} \quad (4)$$

with d_l the detuning and $V_{st,r_l i}$ the matrix element of the strong interaction causing proton capture and resulting resonant transition into the nuclear state $|r_l\rangle$ of ${}_{Z+1}^{A+1}Y$. The origin of the detuning $d_l \leq D_l$ is the energy loss of the proton beam in the target material of thickness D_l usually given in energy units [25]. The $T_{\text{fi}}^{(3,r_l)}$ term will have the dominant $1/\{K_{r_l0}^2 - [k_-^2 + k_+^2 + 2k_-k_+ \cos(\Theta)]\}$ like behaviour, which decreases with increasing Θ . Its Θ dependence is identical with the Θ dependence of the T -matrix element of the second step of the two step process since $K_{r_l0} = \Delta_0 + \varepsilon_{0l} = \Delta$.

In off resonant case

$$T_{\text{fi}}^{(3,n)} = U_{EM,fn}^{(2)} \frac{V_{st,ni}}{i(\varepsilon_{n0} - \Delta_0 - \varepsilon_{0l})}, \quad (5)$$

where $V_{st,ni}$ is the matrix element of the strong interaction causing proton capture and resulting transition into the nuclear state $|n\rangle$ of ${}_{Z+1}^{A+1}Y$. The matrix element $T_{\text{fi}}^{(3,n)}$ (with $n \neq 0, r_l$) of a transition through a non resonant excited state has peaked Θ dependence. The peak angle is determined by (2) using K_{n0} in it. (As it was earlier mentioned, the linked k_- and k_+ values are determined by the $E_- + E_+ = \Delta$ condition.)

e^-e^+ pair creation of peaked Θ dependence can also happen if nuclear transition takes place between nuclear states $|n\rangle$ and $|j\rangle$, when the later goes to the final state due to strong interaction. It is a 4th order process, the T -matrix element of which reads as

$$T_{\text{fi}}^{(4,jn)} = V_{st,fj} \frac{U_{EM,jn}^{(2)}}{i\varepsilon_{j0}} \frac{V_{st,ni}}{i(\varepsilon_{n0} - \Delta_0 - \varepsilon_{0l})}. \quad (6)$$

Since $V_{st}/\varepsilon_{j0} \approx 1$, the magnitude of $T_{\text{fi}}^{(4,jn)}$ is comparable with the magnitude of $T_{\text{fi}}^{(3,n)}$.

Grounds of anomalous e^-e^+ creation.—The comparison of (4), (5) and (6) indicates that the leading T -matrix element belongs to the resonant 3rd order process. Its yield can be comparable with the yield of the two step process since the participation of strong interaction in a higher order process can compensate for its higher order. It can be seen from the ratios of values of the astrophysical factors $S(0)$ of the $d(d,p)^3H$, $d(d,\gamma)^4He$ reactions governed by strong interaction and the ${}^7Li(p,\alpha)^4He$, ${}^7Li(p,\gamma)^8Be$ reactions governed by electromagnetic interaction, which are 10^3 and 40 , respectively [26]. Accordingly, the contribution to the yield of e^-e^+ coincidences due to the higher order processes must not be neglected.

The Θ_m values and the transition wavenumbers K_{n0} , K_{nj} of a given nucleus are connected via (2). In the case of 8Be , the preliminary investigation of Θ_m indicates that besides the actually resonant $T_{\text{fi}}^{(3,r_l)} = r_{r_l} e^{i\varphi_{r_l}}$ term some $T_{\text{fi}}^{(4,jn)} = r_{jn} e^{i\varphi_{jn}}$ terms of the T -matrix element may be significant. Since in these cases $|V_{st,r_i}(\Gamma_{r_l} - id_l) / (d_l^2 + \Gamma_{r_l}^2)| \gg |V_{st,ni} / (\varepsilon_{n0} - \Delta_0 - \varepsilon_{0l})|$ (see (4), (6) and $V_{st}/\varepsilon_{j0} \approx 1$) it is also expected that $r_{r_l} \gg r_{jn}$. These assumptions lead approximately to

$$\left| T_{\text{fi}}^{(3,r_l)} + \sum_{j,n} T_{\text{fi}}^{(4,jn)} \right|^2 = r_{r_l}^2 + \sum_{j,n} 2r_{jn}r_{r_l} \cos(\varphi_{r_l} - \varphi_{jn}). \quad (7)$$

Here, $\varphi_{r_l} = \varphi_{r_l0} - \arctan(d_l/\Gamma_{r_l})$. The d_l dependence of φ_{r_l} indicates that the strength of the interference term significantly depends on the actual penetration depth of the proton into the target if the orders of magnitude of d_l and Γ_{r_l} are comparable.

In the case of 4He the preliminary investigations of Θ_m show that an other 4th order process, the r_{jn} and φ_{jn} values of which are determined by (8), may enter into the

approximate expression (7) of $|T_{\text{fi}}|^2$. In this 4th order process the states j decay to the ground state with the emission of a soft $E2$ photon of energy $\hbar\omega$ ($E2$) allowed by the energy uncertainty E_{un} of the energy measurement of the energy sum of the e^-e^+ pair as $\hbar\omega(E2) = E_{un}$. The corresponding T -matrix element is

$$T_{\text{fi}}^{(4,jn)} = V_{\gamma,fj} \frac{U_{EM,j1}^{(2)}}{i\varepsilon_{j0}} \frac{V_{st,1i}}{\Gamma_1}, \quad (8)$$

with $V_{\gamma,fj}$ the matrix element of $E2$ γ -coupling and Γ_1 the width of state 1.

The Θ dependence of extra e^-e^+ pair creation events due to the term $r_{r_l}^2$ in (7) is identical with the Θ dependence of the second step of the two step process. The Θ dependence of the remaining terms in (7) is of peaked kind. Several transitions of $\hbar c K_{\alpha\beta} < \Delta$ must be taken into account. In consequence of the width $\hbar c \gamma_{\alpha\beta}$ of the transitions and their appearing range $\Theta > \Theta_m$, the peaks overlap.

Discussion of anomalies in the ${}^7Li(p, e^-e^+)^8Be$ reaction.— In the experiment of [16] the $E_{r_1} = 17.640$ MeV (1^+), $\Gamma_{r_1} = 12.2$ keV and the $E_{r_2} = 18.15$ MeV (1^+), $\Gamma_{r_2} = 168$ keV states of 8Be are populated by resonant proton beams of energy 441 keV ($\varepsilon_{01} = 450$ keV, $D_1 = 9$ keV) and 1030 keV ($\varepsilon_{02} = 1100$ keV with $D_2 = 70$ keV), respectively, with all values in the laboratory system. The decay of these states through e^-e^+ emission was studied [14], [16]. The angular (Θ) distribution of the events fulfilling the $E_- + E_+ = \Delta = \Delta_0 + \varepsilon_{0l}$ constraint was measured in the case of both resonantly excited states ($l = 1, 2$). In the case of the 18.15 MeV state extra e^-e^+ events peaked at $\Theta \approx 140^\circ$ were observed but in the angular distribution of the events originating from the 17.640 MeV state no peak appeared, although a slight deviation from the simulated internal pair conversion correlation curve was found at angles above 110° . The deviation was unstructured and some admix of an $E1$ component characteristic of the background could explain it. The observation of a peak at $\Theta \approx 140^\circ$ was attributed to the creation and subsequent e^-e^+ decay of a $J^\pi = 1^+$ boson called X17 particle having rest mass 16.7 ± 0.35 MeV in the decay of the state of 18.15 MeV energy.

As it is mentioned above, beside the two step process in both (17.640 MeV (1^+), $l = 1$ and 18.15 MeV (1^+), $l = 2$) cases, the $T_{\text{fi}}^{(3,r_l)}$ term of $T_{\text{fi}}^{(3)}$ is dominant. The 8Be has excited states $E_1 = 11.35$ MeV (4^+), $E_2 = 16.626$ MeV (2^+), and $E_3 = 16.922$ MeV (2^+) [27]. In the processes which are supposed to give considerable terms to $T_{\text{fi}}^{(4,jn)}$, proton absorption governed by strong interaction leads to states 2 or 3, than e^-e^+ pairs are created in the $2 \rightarrow 1$ or $3 \rightarrow 1$ $E2$ transitions. Finally, strong interaction transition leads to the final state, in which two α particles of sum energy about 0.09184 MeV, which is the decay energy of the ground state of 8Be

FIG. 1: The cp dependence (where p is momentum of the electron/positron) of Θ (given by (2)) of the expected peak in the coincident e^-e^+ pair counting rate in the case of an $E2$ transition of transition energy $\hbar cK_{31} = 5.572$ MeV of ${}^8\text{Be}$. cp is measured in MeV units and Θ is given in degrees.

[28], are created. The values $\hbar cK_{21} = 5.276$ MeV and $\hbar cK_{31} = 5.572$ MeV if $k_- = k_+$ result from (2) that $\Theta_{2,m} = 146.2^\circ$ and $\Theta_{3,m} = 144.2^\circ$, respectively, and if $k_- \neq k_+$ that $\Theta_{j,m} < \Theta_j < 180^\circ$ ($j = 2, 3$) for the angle of the expected peak in the coincident e^-e^+ pair counting rate. The half of the dominant width $\Gamma_1 \approx 3.5$ MeV of state 1 determines the spread of the peaks as about $\pm 12^\circ$. As an example, the $\Theta_3(cp)$ dependence is plotted in the case of $\hbar cK_{31} = 5.572$ MeV in Fig. 1., where p is the momentum of either the electron (p_-) or positron (p_+). The $E_- + E_+ = \Delta$ constraint determines the linked $p_- = \hbar k_-$ and $p_+ = \hbar k_+$ values. Moreover, the $E_{r_1} = 17.640$ MeV (1^+) state can have an upwards $M1$ coupling to the $E_4 = 27.4941$ MeV (0^+) state of width $\Gamma = 5.5$ keV. The corresponding transition energy is $\hbar cK_{40} = 9.854$ MeV to which $\Theta_{4,m} = 114.1^\circ$ belongs. It may be connected to the observed slight deviation obtained above 110° [14].

Supposing that $U_{EM,fr_1}^{(2)} V_{st,r_1i} \approx U_{EM,fr_2}^{(2)} V_{st,r_2i}$ and employing $\sqrt{D_1^2 + \Gamma_{r_1}^2} \ll \sqrt{D_2^2 + \Gamma_{r_2}^2}$ in (4), one has $|T_{\text{fi}}^{(3,r_1)}| \gg |T_{\text{fi}}^{(3,r_2)}|$. Therefore the events due to the $r_{r_1}^2$ term (in the case of $l = 1$) depress stronger the events coming from the cross terms $\sum_{n=2,3} 2r_{1n}r_{r_1} \cos(\varphi_{r_1} - \varphi_{1n})$, which are responsible for the appearance of peaks, than it does in the case of the state $E_{r_2} = 18.15$ MeV (in the case of $l = 2$). All the above harmonize well with the observations of [14], [16].

Discussion of anomalies in the ${}^3\text{H}(p, e^-e^+){}^4\text{He}$ reaction.—In another work [15] the e^-e^+ anomalies in the decay of the 21.01 MeV $0^- \rightarrow 0^+$ transition of ${}^4\text{He}$ were studied. The second excited state of ${}^4\text{He}$ of energy 21.01 MeV (0^-) and center of mass width $\Gamma = 0.84$ MeV [29] was populated in the ${}^3\text{H}(p, \gamma){}^4\text{He}$ reaction with a bombarding energy $\epsilon_p = 900$ keV in the laboratory frame producing an excitation of $E_x = 20.49$ MeV of ${}^4\text{He}$. In this case it is stated [15] that the measured e^-e^+ angular correlation anomalies appeared around a peak of a definite angle 115° . This observation seems to strengthen the X17 boson hypothesis.

The resonant state, the effect of which is taken into account, has energy $E_1 = 20.21$ MeV (0^+) and width $\Gamma_1 = 0.5$ MeV. The ${}^4\text{He}$ has 2^+ excited states of energy $E_2 = 27.42$ MeV, $E_3 = 28.67$ MeV, $E_4 = 29.89$ MeV and of width $\Gamma_2 = 8.69$ MeV, $\Gamma_3 = 3.78$ MeV, $\Gamma_4 = 9.72$ MeV, respectively [29]. The e^-e^+ pair is supposed to be created in the $1 \rightarrow j$ ($j = 2, 3, 4$) $E2$ transitions. The values $\hbar cK_{21} = 7.21$ MeV, $\hbar cK_{31} = 8.46$ MeV and $\hbar cK_{41} = 9.68$ MeV result $\Theta_{2,m} = 138.7^\circ \pm 26^\circ$, $\Theta_{3,m} = 131.2^\circ \pm 12^\circ$ and $\Theta_{4,m} = 123.5^\circ \pm 32^\circ$, respectively, with $k_- = k_+$ and $\Theta_{j,m} < \Theta_j < 180^\circ$ ($j = 2, 3, 4$) if $k_- \neq k_+$ for the angle of the expected peak in the coincident e^-e^+ pair counting rate. The spread of $\Theta_{j,m}$ is determined by the corresponding $\Gamma_j \gg \Gamma_1$ value. As was mentioned above, the energy uncertainty E_{un} of the energy measurement of the energy sum of the e^-e^+ pair allows to take into account those processes in which the states $j = 2, 3$ and 4 decay to the ground state with the emission of a soft $E2$ photon of energy $\hbar\omega(E2) = E_{un}$.

However, similar processes can start from the state of energy $E_1 = 21.01$ MeV (0^-) and of center of mass width $\Gamma_1 = 0.84$ MeV. In this case the 1^- excited states of energy $E_2 = 23.64$ MeV, $E_3 = 24.25$ MeV, $E_4 = 25.95$ MeV, $E_5 = 28.37$ MeV and of width $\Gamma_2 = 6.2$ MeV, $\Gamma_3 = 6.1$ MeV, $\Gamma_4 = 12.66$ MeV, $\Gamma_5 = 3.92$ MeV, respectively, [29] are coupled to state 1 with $M1$ coupling and the states $j = 2, \dots, 5$ decay emitting a soft $M1$ photon of energy $\hbar\omega(M1) = E_{un}$. But the process can also take place through these intermediate states starting from the $E_1 = 20.21$ MeV (0^+) state with $E1$ coupling to them and by emission of a final soft $E1$ photon from these states. Moreover, the $E_1 = 21.01$ MeV (0^-) may have $E1$ coupling with the state of energy $E_5 = 28.31$ MeV (1^+) and of width $\Gamma_2 = 6.2$ MeV too. All the corresponding $\Theta_{j,m}$ values can be determined as well. Thus in this case a great number of reactions can lead to e^-e^+ anomalies.

Summary.—It was raised that e^-e^+ anomalies to the usual IPC decay of an excited nuclear state can be ascribed to reactions of higher order of standard perturbation calculation. The observed anomalous peak [14], [16] is well explained in the case of decay of resonantly excited state of ${}^8\text{Be}$. Qualitative explanation of recent anomalous e^-e^+ observations [15], [16] made in the case of the decay of resonantly excited states of ${}^4\text{He}$ is also

presented. It is concluded that the assumption of X17 particle does not seem to be necessary to explain the observed e^-e^+ anomalies.
