ABSTRACT

Faraday rotation measure at radio wavelengths is commonly used to diagnose large-scale magnetic fields. It is argued that the length-scales on which magnetic fields vary in large-scale diffuse astrophysical media can be inferred from correlations in the observed RM. RM is a variable which can be derived from the polarised radiative transfer equations in restrictive conditions. This paper assesses the usage of RMF (rotation measure fluctuation) analyses for magnetic field diagnostics in the framework of polarised radiative transfer. We use models of various magnetic field configurations and electron density distributions to show how density fluctuations could affect the correlation length of the magnetic fields inferred from the conventional RMF analyses. We caution against interpretations of RMF analyses when a characteristic density is ill defined, e.g. in cases of log-normal distributed and fractal-like density structures. As the spatial correlations are generally not the same in the line-of-sight longitudinal direction and the sky plane direction, one also needs to clarify the context of RMF when inferring from observational data. In complex situations, a covariant polarised radiative transfer calculation is essential to capture all aspects of radiative and transport processes, which would otherwise ambiguate the interpretations of magnetism in galaxy clusters and larger-scale cosmological structures.

Key words: magnetic fields — polarisation — radiative transfer — large-scale structure of Universe — galaxies: clusters: intracluster medium — radiation mechanisms: non-thermal

1 INTRODUCTION

Magnetic fields are present at all scales throughout the Universe, from stars and substellar objects to galaxies, groups, clusters and large-scale structures such as filaments and voids (see e.g. Widrow 2002; Widrow et al. 2012, for reviews). Stellar magnetic fields can be determined spectroscopically, e.g. by measuring Zeeman splitting in the opti-

cal spectral lines for low-mass solar-like stars and magnetic white dwarfs (e.g. Wickramasinghe & Ferrario 2000; Reiners et al. 2013), from separations or locations of the cyclotron harmonic features in the optical/infrared spectra for accreting white dwarfs (e.g. Wickramasinghe & Meggitt 1985; Wu & Wickramasinghe 1990), and from the X-ray spectra of neutron stars (e.g. Nagase et al. 1991; Santangelo et al. 1999; Staubert et al. 2019). Determination of magnetic field properties in larger astrophysical systems is less direct. For magnetic fields in diffuse astrophysical systems, such as the interstellar medium (ISM), intracluster medium (ICM) and

⋆ E-mail: alvina.on.09@ucl.ac.uk (AYLO), y.chan.12@ucl.ac.uk (JYHC), kinwah.wu@ucl.ac.uk (KW)

intergalactic medium (IGM), their properties are often inferred from the polarised radiation traversing and/or emitted from the media. Faraday rotation measure (RM)[1] has been identified as a diagnostic tool for magnetic fields in our Galaxy (see e.g. Simard-Normandin & Kronberg 1980; Han et al. 1999; Brown et al. 2003; Gaensler et al. 2004; Brown et al. 2007; Haverkorn et al. 2008; Oppermann et al. 2012; Han et al. 2015; Han 2017), nearby galaxies (e.g. Gaensler et al. 2005; Beck 2009; Mao et al. 2010, 2017) and also some galaxy clusters (e.g. Carilli & Taylor 2002; Vogt & Enßlin 2003; Clarke 2004; Govoni & Feretti 2004; Brentjens & de Bruyn 2005; Bonafede et al. 2010; Kuchar & Enßlin 2011; Vacca et al. 2018).

Recently, there have also been studies utilising the Faraday rotation of distant polarised radio sources such as quasars (e.g. Kronberg et al. 2008; Xu & Han 2014b) and Fast Radio Bursts (FRBs) (e.g. Xu & Han 2014a; Zheng et al. 2014; Akahori et al. 2016; Ravi et al. 2016; Vazza et al. 2018; Hackstein et al. 2019), as a means to detect and probe cosmological magnetic fields. These fields, permeating the cosmic web of filaments and voids, are weak, and their properties are often inferred statistically (e.g. Akahori et al. 2014; Vernstrom et al. 2019), or indirectly constrained through the non-detection of GeV gamma-rays (e.g. Neronov & Vovk 2010; Taylor et al. 2011; Dermer et al. 2011; Takahashi et al. 2013).

The statistical characterisation of cosmological magnetic fields can be improved with a denser all-sky RM grid from the Square Kilometre Array (SKA), including its pathfinders, the Low Frequency Array (LOFAR), the Murchison Widefield Array (MWA), the Expanded Very Large Array (EVLA), and its precursors, the Australian SKA Pathfinder (ASKAP) and MeerKAT (see e.g. Gaensler et al. 2010; Beck 2015; Johnston-Hollitt et al. 2015). How to properly characterise magnetic fields beyond the scale of galaxy clusters is a challenge in theoretical and observational astrophysics.

Faraday Rotation Measure Fluctuation (RMF) analysis is proposed as a means to probe the structures of large-scale magnetic fields (e.g. Akahori & Ryu 2010; Beck et al. 2013). RM and RMF analyses are essentially based on the theory of polarised radiative transfer under certain restricted conditions. It is therefore important to have a proper understanding of the information we extract from the analyses and under what conditions the analyses enable unambiguous interpretations.

In this paper, we examine the RMF analyses in the context of polarised radiative transfer. We clarify the conditions under which the RMF method will give meaningful inferences and identify the circumstances where we should be cautious when applying the method. We organise the paper as follows. In § 2, we present the formal covariant polarised radiative transfer formulation and show how it reduces to the standard RM under certain conditions. In § 3, we examine the RMF analysis in the context of polarised radiative transfer. We also identify the mathematical and statistical properties of the analyses. In § 4, we construct model density

and magnetic field structures and use them to test the validity of the RMF analyses. We also discuss their astrophysical implications. In § 5, we present our findings and warnings. Unless otherwise stated, this work uses c.g.s. Gaussian units.

2 POLARISED RADIATIVE TRANSFER

2.1 Covariant transport in Stokes-parameter representation

Under the conservation of photon number and the conservation of phase-space volume (see Fuerst & Wu 2004; Younsi et al. 2012), the covariant polarised radiative transfer equation may be expressed as

$$
\frac{\mathrm{d}\mathcal{I}_i}{\mathrm{d}\lambda_a} = -k_\alpha u^\alpha \Big|_{\lambda_{a,co}} \left\{ -\kappa_{ij,co} \left(\frac{I_j}{\nu_{co}^3} \right) + \frac{\epsilon_{i,co}}{\nu_{co}^3} \right\} \tag{1}
$$

(see Chan et al. 2019). Here, ν is the radiation frequency, $\mathcal{I}_i$ is the Lorentz-invariant Stokes vector, λ_a is the affine parameter and $-k_\alpha u^\alpha \big|_{\lambda_{a,co}}$ is the projection factor for a photon with a 4-momentum k^α travelling in a fluid with a 4-velocity u^β. The subscript 'co' denotes that the quantity is evaluated in the reference frame co-moving with the fluid. The transfer matrix, $\kappa_{ij,co}$, accounts for the absorption and Faraday propagation effects, while the emission coefficients are defined by $\epsilon_{i,co}$.

In a Friedmann-Robertson-Walker (FRW) universe, the displacement s as a function of redshift z is given by

$$
\frac{\mathrm{d}s}{\mathrm{d}z} = \frac{c}{H_0} (1+z)^{-1} \left[\Omega_{r,0}(1+z)^4 + \Omega_{m,0}(1+z)^3 + \Omega_{\Lambda,0} \right]^{-\frac{1}{2}} \tag{2}
$$

(see e.g. Peacock 1999), where H_0 is the Hubble parameter, $\Omega_{r,0}$, $\Omega_{m,0}$ and $\Omega_{\Lambda,0}$ are the dimensionless energy densities of relativistic matter and radiation, non-relativistic matter, and a cosmological constant (dark energy with an equation of state of $w \equiv -1$), respectively. The subscript "0" denotes that the quantities are measured at present (i.e. $z = 0$). As such, equation (1) becomes

$$
\frac{\mathrm{d}}{\mathrm{d}z} \begin{bmatrix} \mathcal{I} \\ \mathcal{Q} \\ \mathcal{U} \\ \mathcal{V} \end{bmatrix} = (1+z) \left\{ - \begin{bmatrix} \kappa & q & u & v \\ q & \kappa & f & -g \\ u & -f & \kappa & h \\ v & g & -h & \kappa \end{bmatrix} \begin{bmatrix} \mathcal{I} \\ \mathcal{Q} \\ \mathcal{U} \\ \mathcal{V} \end{bmatrix} + \begin{bmatrix} \epsilon_I \\ \epsilon_Q \\ \epsilon_U \\ \epsilon_V \end{bmatrix} \frac{1}{\nu^3} \right\} \frac{\mathrm{d}s}{\mathrm{d}z} \tag{3}
$$

(Chan et al. 2019), where κ, q, u, v are the absorption coefficients, ϵ are the emission coefficients, f is the Faraday rotation coefficient, and g and h are the Faraday conversion coefficients. The invariant Stokes parameters are related to the usual Stokes parameters by $[\mathcal{I} \, \mathcal{Q} \, \mathcal{U} \, \mathcal{V}]^{\mathrm{T}} = [I \, Q \, U \, V]^{\mathrm{T}}/\nu^3$.

In a local frame, the covariant polarised radiative transfer equation in (3) reduces to the standard polarised radiative transfer equation:

$$
\frac{\mathrm{d}}{\mathrm{d}s} \begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} = - \begin{bmatrix} \kappa & q & u & v \\ q & \kappa & f & -g \\ u & -f & \kappa & h \\ v & g & -h & \kappa \end{bmatrix} \begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} + \begin{bmatrix} \epsilon_I \\ \epsilon_Q \\ \epsilon_U \\ \epsilon_V \end{bmatrix} . \tag{4}
$$

The Stokes parameters $[I, Q, U, V]$ are observables, and their combination gives rise to different derived quantities, including the total degree of polarisation $\Pi_{\mathrm{tot}} =$

---

[1] 'Faraday depth' and 'rotation measure' can only be used interchangeably in the case of a single point source along the line-of-sight.

$\sqrt{Q^2 + U^2 + V^2}/I (\le 1)$, the degree of linear polarisation $\Pi_l = \sqrt{Q^2 + U^2}/I$, the degree of circular polarisation $\Pi_c = V/I$, and the polarisation angle $\varphi = (1/2)\tan^{-1}(U/Q)$ (see e.g. Rybicki & Lightman 1979).

2.2 Derivation of rotation measure

In the absence of absorption and emission, we can set $\kappa = q = u = v = 0$ and $[\epsilon_I, \epsilon_Q, \epsilon_U, \epsilon_V] = 0$, therefore imposing $dI/ds = 0$, and

$$\frac{d}{ds}\begin{bmatrix} Q \\ U \\ V \end{bmatrix} = -\begin{bmatrix} 0 & f & -g \\ -f & 0 & h \\ g & -h & 0 \end{bmatrix}\begin{bmatrix} Q \\ U \\ V \end{bmatrix} . \tag{5}$$

In situations where the circular polarisation is insignificant and the conversion between linear and circular polarisation is negligible, we may consider only two linearly polarised Stokes components in the polarised radiative transfer calculation. The polarised radiative transfer equation then takes a simplified form:

$$\frac{d}{ds}\begin{bmatrix} Q \\ U \end{bmatrix} = -\begin{bmatrix} 0 & f \\ -f & 0 \end{bmatrix}\begin{bmatrix} Q \\ U \end{bmatrix} . \tag{6}$$

The Faraday rotation coefficient f is the sole parameter in this equation. It is determined by the properties of free electrons and the magnetic field along the line-of-sight.

An astrophysical plasma may contain both thermal and non-thermal electrons. If the fraction of non-thermal electrons is small, the conversion between the two linearly polarised Stokes components is determined mainly by the thermal electrons. With only thermal electrons present, the Faraday rotation coefficient is

$$f_{th} = \frac{\omega_p^2 \cos\theta}{c\,\omega_B}\left(\frac{\omega_B^2}{\omega^2 - \omega_B^2}\right) \tag{7}$$

(Pacholczyk 1977), where $\omega = 2\pi\nu$ is the angular frequency of radiation, $\omega_p = (4\pi n_{e,th}e^2/m_e)^{1/2}$ is the plasma frequency, $\omega_B = (eB/m_e c)$ is the electron gyro-frequency, $n_{e,th}$ is the thermal electron number density, B is the magnetic field strength and θ is the angle between the magnetic field vector and the line-of-sight. Here, c is the speed of light, e is the electron charge, and m_e is the electron mass. In the high-frequency limit (i.e. $\omega \gg \omega_B$), the Faraday rotation due to only thermal electrons can be expressed as,

$$f_{th} = \frac{1}{\pi}\left(\frac{e^3}{m_e^2 c^4}\right)n_{e,th}\,B_\parallel\,\lambda^2 , \tag{8}$$

where $B_\parallel = |\boldsymbol{B}|\cos\theta$ is the magnetic field along the line-of-sight and $\lambda = 2\pi c/\omega$ is the wavelength of radiation. The corresponding expression for Faraday rotation due to only non-thermal electrons is

$$f_{nt} = \frac{1}{\pi}\left(\frac{e^3}{m_e^2 c^4}\right)\zeta(p, \gamma_i)\,n_{e,nt}\,B_\parallel\,\lambda^2 , \tag{9}$$

where the factor,

$$\zeta(p, \gamma_i) = \frac{(p-1)(p+2)}{(p+1)}\left(\frac{\ln\gamma_i}{\gamma_i^2}\right) , \tag{10}$$

for $p > 1$, assuming an isotropic distribution of non-thermal electrons with a power-law energy spectrum of index p

(Jones & O'Dell 1977). The number density of non-thermal electrons is $n_{e,nt}$, and γ_i is their low-energy cut-off.

In a plasma consisting of thermal electrons plus non-thermal electrons, the relative strength of their contributions to the Faraday rotation is therefore

$$\frac{f_{nt}}{f_{th}} \approx \zeta(p, \gamma_i)\left(\frac{n_{e,nt}}{n_{e,th}}\right) , \tag{11}$$

provided that neither $n_{e,nt}$ nor $n_{e,th}$ correlates or anti-correlates significantly with $B_\parallel$[2].

From the restrictive polarised radiative transfer equation (6) which only has two linear Stokes components, it can easily be shown that the change in the linear polarisation angle along the line-of-sight is

$$\frac{d\varphi}{ds} = \frac{1}{2}\left(\frac{1}{U^2 + Q^2}\right)\left(Q\frac{dU}{ds} - U\frac{dQ}{ds}\right) = \frac{f}{2} . \tag{12}$$

With only thermal electrons in a sufficiently weak magnetic field where $\omega_B \ll \omega$, a direct integration of equation (12) with $f = f_{th}$ yields

$$\varphi(s) = \varphi_0 + \frac{2\pi e^3}{m_e^2(c\,\omega)^2}\int_{s_0}^s ds'\, n_{e,th}(s')\, B_\parallel(s') . \tag{13}$$

Rotation measure (RM) is defined as

$$\mathcal{R} = (\Delta\varphi)\lambda^{-2} = (\varphi - \varphi_0)\,\lambda^{-2} . \tag{14}$$

The polarised radiative transfer equations (4), (5) and (6) are linear, thus the contributions to the Faraday rotation coefficient by a collection of thermal and non-thermal electrons are additive. The RM for radiation traversing a magnetised plasma between an interval s_0 and s is therefore

$$\mathcal{R}(s) = \frac{e^3}{2\pi m_e^2 c^4}\int_{s_0}^s ds'\, n_e(s')\,\Theta(s')\, B_\parallel(s') , \tag{15}$$

where n_e is the total electron number density, and $\Theta(s) = 1 - \Upsilon(s)\left[1 - \zeta(p, \gamma_i)\right]\big|_s$ is the weighting factor of n_e contributing to the Faraday rotation effect, accounting for both thermal and non-thermal electron populations, with $\Upsilon(s)$ the local fraction of non-thermal electrons. If only thermal electrons are present, $\Upsilon(s) = 0$ such that $\Theta(s) = 1$, hence recovering the widely-used formula in RM analysis of magnetised astrophysical media (see e.g. Carilli & Taylor 2002):

$$\mathcal{R}(s) = 0.812\int_{s_0}^s \frac{ds'}{\text{pc}}\left(\frac{n_{e,th}(s')}{\text{cm}^{-3}}\right)\left(\frac{B_\parallel(s')}{\mu\text{G}}\right)\text{rad m}^{-2} . \tag{16}$$

3 ROTATION MEASURE FLUCTUATIONS

3.1 Computing rotation measure in a discrete lattice

Practical calculations of polarised radiative transfer in an inhomogeneous medium often require sampling the medium

---

[2] A similar relation was given in Jones & O'Dell (1977) for the relative contributions of relativistic and thermal electrons to the Faraday rotation. Their relation is expressed in terms of the spectral index α of the optically thin power-law synchrotron spectrum. The relation (11) here is expressed in terms of the power-law index p of the electron energy distribution, which is intrinsic to the magneto-ionic medium. Note that $\alpha = (p-1)/2$.

into discrete segments that have small internal variations in physical properties. Suppose we divide the radiation propagation path length L into N intervals of lengths Δs, i.e. $L = \sum_{i=1}^{N} \Delta s(i)$. Then the integral in equation (15) can be approximated by summing contributions from all segments

$$\mathcal{R}(s) = \frac{e^3}{2\pi m_e^2 c^4} \sum_{i=1}^{N} \Delta s(i) \, n_e(i) \, \Theta(i) \, B_\parallel(i) \, , \qquad (17)$$

where n_e, Θ and $B_\parallel$ are evaluated at the centre of each interval, s_i. If the magnetic fields have uniform strengths and unbiased random orientations, then $B_\parallel$ will have a symmetric probability distribution: $P(B_\parallel) = P(-B_\parallel)$. With $\Delta s > 0$, $n_e \geqslant 0$ and $\Theta \in [\,0,1\,]$, the symmetry in the probability distribution of $B_\parallel$ implies that the expectation value of RM

$$\langle \mathcal{R} \rangle = \frac{e^3}{2\pi m_e^2 c^4} \sum_{i=1}^{N} \langle \Delta s \, n_e \, \Theta \, B_\parallel \rangle \big|_i \;\; = \;\; 0 \, , \qquad (18)$$

where $\langle ... \rangle$ denotes the ensemble average of the variables.

Supposing that n_e, Θ and $B_\parallel$ are incoherent among the intervals Δs, then n_e, Θ and $B_\parallel$ are the only independent variables for computing the RM of a cell defined by an interval. Moreover, if the medium does not evolve during the radiation's propagation, n_e, Θ, $B_\parallel$ and their products are also exchangeable variables. Under the ergodic condition, the ensemble averages of independent and exchangeable variables can be replaced by the averages of over the path length, i.e. for a sufficiently large N,

$$\langle X \rangle = \frac{1}{N} \sum_{j=1}^{N} X(s_j) \;\; = \;\; \langle X(s_j) \rangle_s \, . \qquad (19)$$

Thus,

$$\langle \mathcal{R} \rangle = \frac{e^3}{2\pi m_e^2 c^4} N \langle \Delta s \, n_e \, \Theta \, B_\parallel \rangle_s \;\; = \;\; 0 \, . \qquad (20)$$

Moreover, if $\mathbf{B}$, n_e and Θ do not correlate with each other, we have

$$\langle \mathcal{R} \rangle = \frac{e^3}{2\pi m_e^2 c^4} N \langle \Delta s \rangle_s \langle n_e \rangle_s \langle \Theta \rangle_s \langle B_\parallel \rangle_s \;\; = \;\; 0 \, . \qquad (21)$$

3.2 Rotation measure fluctuations as a restrictive autoregression (AR) process

Note that an observable $\tilde{O}_k$ on the lattice grid k in an AR(1) (autoregression of order one) process on a 1-D lattice is given by the recursive relation:

$$\begin{aligned} \tilde{O}_k &= \rho \, \tilde{O}_{k-1} + \varepsilon_k \\ &= \rho \left(\rho \, \tilde{O}_{k-2} + \varepsilon_{k-1} \right) + \varepsilon_k \\ &\cdots\cdots \\ &= \rho^m \, \tilde{O}_{k-m} + \sum_{j=0}^{m-1} \rho^j \, \varepsilon_{k-j} \end{aligned} \qquad (22)$$

(see e.g. Box & Jenkins 1976; Anderson 1976; Grunwald et al. 1995), where ρ is a parameter, and ε_k is an iid (independent, identically distributed) variable with an expectation value $E(\varepsilon_k) = \langle \varepsilon_k \rangle = 0$ and a variance $Var(\varepsilon_k) = [\sigma(\varepsilon_k)]^2$. For a finite or semi-infinite lattice, which is truncated at

$j = 0$, at which the observable $\tilde{O}_0$ is well defined, we can rewrite equation (22) as

$$\tilde{O}_k = \rho^k \, \tilde{O}_0 + \sum_{j=1}^{k} \rho^{k-j} \, \varepsilon_j \, . \qquad (23)$$

For a polarised radiation's propagation path consisting of N segments with approximately coherent Faraday rotation properties, the polarisation angle at the end of the kth segment is given by

$$\begin{aligned} \varphi_k &= \varphi_{k-1} + \Delta\varphi_k \\ &= \varphi_{k-2} + \Delta\varphi_{k-1} + \Delta\varphi_k \\ &\cdots\cdots \\ &= \varphi_0 + \sum_{j=1}^{k} \Delta\varphi_j \, , \end{aligned} \qquad (24)$$

where $\Delta\varphi_k$ is the rotation of the polarisation angle in the kth segment, and the polarisation angle measured by the observer is simply φ_N. Comparing equations (24) and (23) reveals that the evolution of the polarisation angle along the radiation's propagation is an AR(1) process with a constant parameter $\rho = 1$, provided that $\langle \Delta\varphi_j \rangle = 0$ and that $Var(\Delta\varphi_j)$ is well defined and computable. An AR(1) process is a Markov process (see Anderson 1976), and an AR(1) process with $\rho = 1$ is also known as a simple random-walk.

The rotation measure across the propagation path of the radiation is $\mathcal{R}\big|_N = (\varphi_N - \varphi_0)\lambda^{-2}$. Hence, from equation (20), we obtain

$$\left\langle \sum_{j=1}^{N} \Delta\varphi_j \right\rangle_s = \lambda^2 \, \langle \mathcal{R} \rangle_s \;\; = \;\; 0 \, . \qquad (25)$$

As the expectation value and the variance of $(\varphi_N - \varphi_0)$ are

$$\mathrm{E}\big[\varphi_N - \varphi_0 \big] = 0 \, ; \qquad (26)$$

$$\mathrm{Var}\big[\varphi_N - \varphi_0 \big] = N \, \sigma^2 \, , \qquad (27)$$

respectively, with $\sigma^2 = \langle \Delta\varphi_j{}^2 \rangle$, the standard deviation of $\mathcal{R}$ in the radiation's propagation direction is therefore

$$\begin{aligned} \sigma_{\mathcal{R}} &= \sqrt{N} \, \left[\langle \Delta\varphi_j{}^2 \rangle \right]^{1/2} \lambda^{-2} \\ &= \frac{e^3 \sqrt{N}}{2\pi m_e^2 c^4} \, \left[\langle \Delta s^2 \, n_e^2 \, \Theta^2 \, B_\parallel{}^2 \rangle \right]^{1/2} \\ &= \frac{e^3 \sqrt{N}}{2\pi m_e^2 c^4} \, \left[\langle \Delta s^2 \, n_e^2 \, \Theta^2 \, B_\parallel{}^2 \rangle_s \right]^{1/2} \, . \end{aligned} \qquad (28)$$

Note that the rotation measure fluctuation along a radiation propagation path consisting of coherent segments is proportional to the square root of the number of the segments ($\sqrt{N} = \sqrt{L/\langle \Delta s \rangle_s}$), a characteristic of a simple random-walk process, where the root mean square displacement is proportional to the square root of the number of steps. Here, the root mean square of properties within a step size is $\left[\langle \Delta s^2 \, n_e^2 \, \Theta^2 \, B_\parallel{}^2 \rangle_s \right]^{1/2}$. In the specific condition that the interval segments have equal length, $\overline{\Delta s}$, and $(n_e \Theta)$ does not vary along the line-of-sight, equation (28) becomes

$$\sigma_{\mathcal{R}} = \frac{e^3}{2\pi m_e^2 c^4} \sqrt{\frac{L}{\overline{\Delta s}}} \, \overline{\Delta s} \, n_e \, \Theta \left[\langle B_\parallel{}^2 \rangle_s \right]^{1/2} \, . \qquad (29)$$

A similar but more rigorous expression can be obtained

if there is no correlation between electron number density and the magnetic fields. In this case, equation (28) becomes

$$\sigma_{\mathcal{R}} = \frac{e^3}{2\pi m_e^2 c^4} \sqrt{\frac{L}{\overline{\Delta s}}} \, \overline{\Delta s} \, \overline{n_e \Theta} \left[\left\langle B_{\parallel}^2 \right\rangle_s \right]^{1/2} , \qquad (30)$$

with $\overline{n_e \Theta}$ denoting the mean value of $(n_e \Theta)$. Additionally, in the presence of only thermal electrons, then $\Theta = 1$ uniformly, and

$$\sigma_{\mathcal{R}} = \frac{e^3}{2\pi m_e^2 c^4} \sqrt{\frac{L}{\overline{\Delta s}}} \, \overline{\Delta s} \, \overline{n}_{e,th} \, B_{\parallel rms}$$

$$= 0.812 \sqrt{\frac{L}{\overline{\Delta s}}} \left(\frac{\overline{\Delta s}}{pc} \right) \left(\frac{\overline{n}_{e,th}}{cm^{-3}} \right) \left(\frac{B_{\parallel rms}}{\mu G} \right) \text{ rad m}^{-2} . \qquad (31)$$

Most observational or numerical studies use either one of the expressions given in equations (30), and (31) in their RM fluctuation analysis. These include investigations of magnetic fields in galaxy clusters or in large-scale structures (e.g. Sokoloff et al. 1998; Blasi et al. 1999; Dolag et al. 2001; Govoni & Feretti 2004; Subramanian et al. 2006; Cho & Ryu 2009; Sur 2019). Note that the two expressions above are not always explicitly distinguished in studies of RM fluctuations. The $\sigma_{\mathcal{R}}$ derivations from equation (28) to equations (29), (30) and (31) rely on subtly different assumptions regarding the electron density spatial distributions and their relation or correlation with the magnetic fields. For instance, it matters whether local quantities are multiplied before spatial averaging, or averaged separately then multiplied. Note also that, in reality, the condition of constant electron number density, or/and the condition of electron number density and magnetic field being uncorrelated, are generally not satisfied. We should therefore bear in mind which underlying assumptions have been used, and they should be stated explicitly when interpreting the magnetic field structures using the observed RM statistics. Furthermore, while $\sigma_{\mathcal{R}}$ is observed on the sky plane, it is calculated over the radiation's propagation path, with the application of a random walk model along the line-of-sight and invoking other explicit assumptions we made above.

3.3 Fluctuations of density and magnetic fields in parallel and in perpendicular directions

The polarisation of radiation at a location on the sky plane, and hence the celestial sphere, is determined by the magneto-ionic properties of plasma along the line-of-sight (specified by the propagation unit vector $\hat{k}$). On cosmological scales, the transfer of radiation along the line-of-sight is the transfer of radiation from the past to the present. Consequently, the statistical properties of the observed polarisation signatures across a sky plane depend on two factors: (i) the spatial variations of the magneto-ionic plasma properties at different cosmological epochs, and (ii) the temporal variations of the magneto-ionic plasma properties as the Universe evolved. Note that these two factors are not always mutually independent. It is their convolution that will determine the variations of the observable variables along the ray as it propagates (i.e. in $\hat{k}$ direction, denoted by $\parallel$) and the variations of the observable variables among the collection of rays reaching the sky plane (i.e. in directions $\perp$ to $\hat{k}$). More

Figure 1. Illustration of a case where $\sigma_{x,\perp} \neq \sigma_{x,\parallel}$, emphasising that polarisations are modified along the line-of-sight, but what we observe is only the resulting angle on the orthogonal image plane. In this demonstration, line-of-sight **A** exhibits two characteristic lengths of polarisation fluctuation, $\ell_{c_1,\parallel}$ and $\ell_{c_2,\parallel}$, as illustrated by the number of cells spanning a full rotation, while for line-of-sight **B**, $\ell_{c_3,\parallel}$. None of these coincides with $\ell_{c,\perp}$ on the image plane.

importantly, there is no guarantee that these two types of fluctuations are statistically identical. In other words, if we use a simple representation with two independent orthogonal components, designated to be parallel and perpendicular to $\hat{k}$, we cannot simply assume that $\sigma_{x,\perp} = \sigma_{x,\parallel}$, where the quantity $x \in \{ Q, U, V, \Delta\varphi, \text{ or } \mathcal{R} \}$. In general, we have two separate correlation lengths, $\ell_{\parallel}$ and $\ell_{\perp}$, for each plasma quantity, e.g. the electron number density n_e (which is a scalar) and the magnetic field $\boldsymbol{B}$ (which is a vector). See Fig. 1 for an illustration.

The question now is whether we can take a correlation length derived from a polarisation signature across the sky plane as the characteristic correlation length scale over which the cosmological magnetic fields vary spatially or, alternatively, over time. Firstly, the polarised radiative transfer equation shows that the rotation of the polarisation angle only depends on the magnetic field parallel to the line-of-sight, i.e. $\boldsymbol{B}_{\parallel}$. The perpendicular component of the magnetic field $\boldsymbol{B}_{\perp}$ is irrelevant in this respect. Therefore, in each individual ray, the local polarisation fluctuations are only caused by the fluctuations of the parallel field component, $\boldsymbol{B}_{\parallel}$, and the fluctuations of the electron number density n_e and energy distribution.

Secondly, the fluctuations of polarisation properties along individual rays are not directly observable. Instead, observations reveal a "polarisation map" on the celestial sphere, which represents the polarisation signatures of a collection of end-points of the path-integrated polarised rays. If the rays are independent, we would observe variations in the polarisation signatures, such as the RM fluctuations, even when the magneto-plasma is statistically spatially uniform at any cosmological epoch. In this situation, the observed RM fluctuations reflect the convolution of the fluctuations in $|\boldsymbol{B}_{\parallel}|$ and n_e along the line-of-sight, i.e. not simply an effect arising from the presence of spatial structures. Note that there are additional subtleties in assessing the local variations of polarisation signature along a ray. Suppose that the electron number density and its energy spectrum are uniform in both space and time, there still exists an ambiguity in determining the fluctuation of the magnetic field $\boldsymbol{B}$, as the
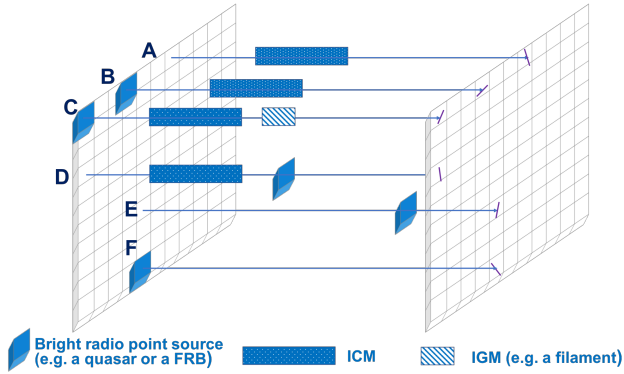

Figure 2. Illustration of how different astrophysical conditions give rise to different polarisation fluctuations due to e.g. (i) the presence or absence of bright background sources (lines-of-sight **A** and **B**), (ii) the presence or absence of multiple sources with different Faraday depths (lines-of-sight **B** and **C**), (iii) different positional orders of sources (lines-of-sight **B** and **D**), and (iv) change of radiation frequency due to the Universe's expansion, and/or the presence of sources either at low or high redshift (lines-of-sight **E** and **F**).

polarisation angle rotates depending on value of $|\boldsymbol{B}_\parallel|$, which equals to $|\boldsymbol{B}|\cos\theta$, at an unknown angle $\theta = \cos^{-1}(\hat{\boldsymbol{k}} \cdot \hat{\boldsymbol{B}})$. Thus, there are two aspects in the magnetic field fluctuations, one concerning the field magnitudes, and another concerning the field orientations. Magnitude fluctuations and orientation fluctuations can arise from different processes. For instance, the variations in the magnetic field orientation $\hat{\boldsymbol{B}}$ may indicate the characteristic size of the astrophysical system or the magnetic sub-domain of the cosmic magneto-ionic plasma, while the variations in the magnetic field magnitude $|\boldsymbol{B}|$ along the line-of-sight would inform us about the changes in the global magnetic energy density as the Universe evolves. Fluctuations of $\hat{\boldsymbol{B}}$ and those of $|\boldsymbol{B}|$ can arise from different mechanisms and/or operate on different characteristic time scales. Thus, $\sigma_{|\boldsymbol{B}|}\big|_{\parallel,\,\text{or}\,\perp} = \sigma_{\hat{\boldsymbol{B}}}\big|_{\parallel,\,\text{or}\,\perp}$ do not usually hold.

Fig. 2 illustrates some example scenarios that give rise to different observational polarisation signals[3]. The types and number of sources, and the magneto-ionic properties of the intervening plasmas vary along each line-of-sight and vary among the lines-of-sight across the sky. Magnetic fields are vectors, and therefore possess two structural traits: one in the field strength (or energy density), and another in the field orientation. Both aspects are essential to determine the properties of all-sky polarisation. Faraday rotation also depends on the line-of-sight electron number densities, and the electron number densities and the magnetic fields are usually interdependent. Depending on what mechanisms generate and/or amplify the magnetic fields, local and non-

---

[3] Inferring the magneto-ionic properties of the line-of-sight sources and the intervening plasmas from the polarised sky data, which has a (2 + 1)-D structure, where the "+1" corresponds to the time axis or cosmological redshift, is an inverse problem. In forward theoretical modelling, the polarisation signals are, however, determined by the cosmological polarised radiative transfer, which is in a (3 + 1)-D format, where the line-of-sight direction also aligns with the axis of cosmological time.

local correlations between the two quantities could occur. As such, we cannot simply take the face values of the correlation lengths obtained from RM fluctuation analyses as they appear, without careful consideration. In the analysis of cosmological-scale magnetism we also need to consider effects due to cosmological expansion. Large-scale magnetic fields would evolve with the cosmological structure (see e.g. Dolag et al. 2005; Cho & Ryu 2009; Ryu et al. 2012; Barnes et al. 2012, 2018; Marinacci et al. 2015; Katz et al. 2019). Covariant PRT calculations (Chan et al. 2019) are therefore essential, if we wish to take full account of all the magneto-ionic plasma effects throughout the evolutionary history of the Universe, providing insights and theoretical bases for proper interpretation of the statistical RM analyses of the observed polarised sky.

4 RESULTS AND DISCUSSION: VARIANCE OF RM FLUCTUATIONS

4.1 Assessing the rotation measure fluctuation approach

The formula in equation (31) is commonly used in RM fluctuation analysis for probing the structures in large-scale magnetic fields. Here we assess when the formula is justified and when it deserves caution. The formula contains two variables related to n_e and $\boldsymbol{B}$, and our assessment will focus on their spatial distribution properties. We perform Monte-Carlo simulations to compute the RM fluctuations. We consider simulated cubes of Mpc size with mock thermal electron number density (d) and magnetic field strength (b) with uniform (U), Gaussian (G), fractal (F) and log-normal (L) distributions. Each simulation is specified by a 4-letter label. For instance, 'UdGb' stands for uniformly-distributed densities and gaussian-distributed magnetic field strengths with random orientations. The Mersenne Twister (MT, Matsumoto & Nishimura 1998) is implemented to generate uniformly-distributed pseudo-random numbers, $Z \in (\,0,1\,]$, which transform into the G, F and L distributed variates according to the specification.

The cubes are discretised into 256^3 voxels, each having an equal linear length $\overline{\Delta s}$ on the three sides. The magnetic field and the thermal electrons are specified according to the assigned distributions. Their values are normalised such that they are of a similar order to those observed in galaxy clusters: $\langle n_{e,\text{th}} \rangle = 10^{-3}\,\text{cm}^{-3}$, $B_{\text{rms}} = 1\,\mu\text{G}$ and $L = 1\,\text{Mpc}$ (e.g. Cho & Ryu 2009). The total thermal electron number density and the total magnetic energy in the whole simulation box, regardless of the magneto-ionic distribution, are $256^3 \times 10^{-3} = 16777.216\,\text{cm}^{-3}$ and $|\boldsymbol{B}|^2 = 256^3 = 16777216\,(\mu\text{G})^2$, respectively. This ensures uniformity between the model cubes, which enables direct comparisons between the simulations.

To compute the RM, we sum the contributions along the lines-of-sight, $\boldsymbol{x}$, $\boldsymbol{y}$ and $\boldsymbol{z}$, using the discretised expression of equation (16) in terms of lattice units (i,j,k),

$$\mathcal{R}_\perp = 0.812 \sum_\parallel \frac{\overline{\Delta s}}{\text{pc}} \left[\left(\frac{n_{e,\text{th}}(i,j,k)}{\text{cm}^{-3}} \right) \left(\frac{B(i,j,k)}{\mu\text{G}} \right) \right]_\parallel \text{rad m}^{-2} \ . \quad (32)$$

The standard deviation $\varsigma_{\mathcal{R}_\perp}$ across the simulated sky-plane is then computed and compared to the longitudinal standard deviation given in equation (31).

4.1.1 Modelling magnetic fields

We consider magnetic fields with random orientations and no spatial correlation. They are therefore unit vectors: $\hat{B}_x = \sin\theta\cos\phi$, $\hat{B}_y = \sin\theta\sin\phi$ and $\hat{B}_z = \cos\theta$, with $\cos\theta \in (-1, 1]$ and $\phi \in (0, 2\pi]$ in a uniform distribution. The field strength on the other hand has a uniform, non-solenoidal (Ub*) or a uniform, solenoidal (Ub) or a Gaussian (Gb) distribution. The normalisation is such that the r.m.s. value $B_{rms} = 1\,\mu G$. Hence, we have $B_{\parallel rms} = B_{rms}/\sqrt{3} \simeq 0.577\,\mu G$. The Gaussian distribution is generated using the Box-Muller transform in the usual Monte-Carlo simulations. The simulated magnetic fields are then cleaned in Fourier space with the application of a divergence-free ($\nabla \cdot \boldsymbol{B} = 0$) filter: $B_i(k_m) = (\delta_{ij} - k_i k_j/k^2)\tilde{B}_j(k_m)$ (Balsara 1998). As the process removes the field component parallel to $\boldsymbol{k}$, the total magnetic energy stored in the cube shrinks to 2/3 of its original value. To compensate for the energy loss by the filtering process, the field components are rescaled by a factor of $\sqrt{3/2}$. An inverse Fourier transform is then conducted to obtain the divergence-free ('solenoidal') magnetic field in the configuration space (see Appendix A).

We also note that the divergence-free filtering process introduces a residual dipole, which has a preferred orientation, depending on how the filtering process is executed. To suppress this dipole structure, we employ a quick-fix solution[4] using a superposition of three independent, orthogonal field realisations. We then renormalise the resultant field from the superposition by a $\sqrt{1/3}$ scaling factor. Since the realisations prepared as such are divergence free in real (configuration) and Fourier space, their linear superpositions in real and Fourier space[5] will also be divergence free.

4.1.2 Modelling free-electron number density

We consider four model electron number density distributions: uniform (Ud), Gaussian (Gd), log-normal (Ld) and fractal (Fd). For the uniform distribution, the electron number density is set to be 1 unit in each cell. For the Gaussian distribution, we apply a Box-Muller transform, setting the standard deviation to 0.2 times the mean $10^{-3}\,cm^{-3}$, so that there are only a few negative numbers, which can be converted to positives by simply taking the absolute. The

log-normal distribution is generated by taking the exponential function of Gaussian-distributed random numbers. For a fractal model, we generate random phases (k_x, k_y, k_z) in Fourier space. We then apply a power-law filter $|\boldsymbol{k}|^{-5/3}$ to mimic a Kolmogorov-like turbulence spectrum (1941a; 1941b). Simulations predict various kinds of turbulence in clusters and cosmic filaments (e.g. Iapichino et al. 2011). Scaling laws originally derived for incompressible media also turn out to be a good approximation for compressible turbulence in subsonic regions of real observed or numerically simulated IGM (see e.g. Schuecker et al. 2004; Miniati 2014; Nakwacki et al. 2016; White et al. 2019).[6] In our model, we apply frequency cutoffs as in Saxton et al. (2005): we impose $k_{max} = N/2$ to prevent excessively sharp contrasts at voxel scale, and $k_{min} = 8$ to prevent any single density peak dominating. The inverse Fast Fourier Transform yields a fractal-like spatial structure with normally distributed local values $\mathcal{N}$. Dimensionless positive densities are obtained by taking $\exp(\alpha\mathcal{N}/\mathcal{N}_{max})$, where the contrast factor $\alpha = 4$ and $\mathcal{N}_{max}$ is a fiducial maximum fluctuation (Elmegreen et al. 1989; Elmegreen 2002). Lastly we obtain the various astrophysical configurations of thermal electron number densities by normalising $\langle n_{e,th}\rangle$ of each box to $10^{-3}\,cm^{-3}$.

4.1.3 RM dependence on the density and magnetic field structures

We calculate synthetic RM maps by integrating along lines of sight $\boldsymbol{x}, \boldsymbol{y}$ and $\boldsymbol{z}$ using equation (32) through various distributions of thermal electron number densities and magnetic field strengths. The RM maps from the GdGb and UdUb* distributions are indistinguishable from a simple eyeball test (see Fig. 3), even though the maps are generated from distinct distributions of number densities and magnetic field strengths. GdGb is commonly assumed in astrophysical scenarios, whereas UdUb* is simply unrealistic because the magnetic fields are non-solenoidal. The resulting RM maps are similar across all lines of sight, implying that it is non trivial to characterise the thermal number densities and the magnetic field strengths from the observed RM fluctuations alone.

We compare models quantitatively in Table 1. We calculate the line-of-sight longitudinal dispersions using equation (31) and obtain $\sigma_{\mathcal{R}}^{xy} \simeq \sigma_{\mathcal{R}}^{xz} \simeq \sigma_{\mathcal{R}}^{yz} \simeq 29.3\,rad\,m^{-2}$ in all cases, indicating that this type of RM fluctuation formula cannot distinguish between the different distributions of number densities and magnetic field strengths. The tiny variations in the least significant figures of $\sigma_{\mathcal{R}}^{xy}$, $\sigma_{\mathcal{R}}^{xz}$ and $\sigma_{\mathcal{R}}^{yz}$ are due to the numerical noise and random differences in the generated realisations. Table 1 also shows that line-of-sight and sky transverse fluctuations match reasonably well ($\sigma_{\mathcal{R}} \simeq \varsigma_{\mathcal{R}}$) in the cases of UdUb*, UdUb and UdGb, indicating that the widely-used RM fluctuation formula is applicable for uniformly-distributed densities and magnetic field strengths with uniform distributions and Gaussian distributions. However, for GdUb, GdGb, FdUb, FdGb, LdUb

---

[4] In a more proper treatment, we would need a superposition of three anti-parallel pairs of independent, orthogonal field realisations in order to completely remove the dipole. The process would then leave a residual quadrupole. Nonetheless the quick-fix solution that we employ to suppress the dipole is sufficient for the purpose of this demonstrative study. In reality, the divergence filtering is not always necessary before radiative transfer, as the magnetic fields output by a detailed magneto-hydrodynamic simulation (see e.g. Marinacci et al. 2015, 2018; Barnes et al. 2018) should be divergence free, at least in principle.

[5] Note that in the execution of Fourier transform process, we do not consider an infinite span of the configuration space. The restriction of the electron number density and magnetic field structure within a finite volume is equivalent to the introduction of a cubic window function to an infinite configuration space. Thus, the density distribution and the magnetic field structure that we obtain in the Fourier representation are the convolutions of the cubic window function with the electron number density distribution and the magnetic field structure.

[6] The alternative extreme, of shock-compressed supersonic turbulence, yields steeper spectra $\sim k^{-2.1}$; e.g. Lee et al. (1991); Federrath (2013).

and LdGb; $\sigma_{\mathcal{R}} < \varsigma_{\mathcal{R}}$, meaning that the RM fluctuation formula is inadequate in situations with Gaussian, fractal or log-normal density distributions. The disagreement between $\sigma_{\mathcal{R}}$ and $\varsigma_{\mathcal{R}}$ is at the level of $\sim 2\%$, $\sim 25\%$ and $\sim 40\%$ respectively for G, F and L density models. For a comparison, we note that Bhat & Subramanian (2013) calculated the evolving RM properties of the ICM in fluctuation dynamo simulations, and found that $\varsigma_{\mathcal{R}}$ was $\sim 10\%$–15% above some statistical indicators of RMF ($\approx \sigma_{\mathcal{R}}$). In their models, the evolving magnetic features seemed to be more influential than the density variations.

Notably, both our RMS model and explicit RT simulation cannot distinguish the difference between solenoidal and non-solenoidal fields, as shown by $\sigma_{\mathcal{R}}(\mathrm{UdUb^*}) \simeq \sigma_{\mathcal{R}}(\mathrm{UdUb}) \simeq 29.3\,\mathrm{rad\,m^{-2}}$. Our calculations also show that the sky planar fluctuations: $\varsigma_{\mathcal{R}}(\mathrm{UdUb^*}) \simeq \varsigma_{\mathcal{R}}(\mathrm{UdUb}) \simeq \varsigma_{\mathcal{R}}(\mathrm{UdGb})$, $\varsigma_{\mathcal{R}}(\mathrm{GdUb}) \simeq \varsigma_{\mathcal{R}}(\mathrm{GdGb})$, $\varsigma_{\mathcal{R}}(\mathrm{FdUb}) \simeq \varsigma_{\mathcal{R}}(\mathrm{FdGb})$ and $\varsigma_{\mathcal{R}}(\mathrm{LdUb}) \simeq \varsigma_{\mathcal{R}}(\mathrm{LdGb})$. The Fourier transform and inverse Fourier transform are part of the divergence cleaning process. Note that the Fourier transform of uniformly-distributed fields in a finite volume gives a 3-D sinc function (in the Cartesian coordinate).

For a more detailed characterisation of the RM distributions, we calculate the histograms and cumulative distribution functions (CDFs) of the RM maps from every line of sight through the UdUb*, UdUb, UdGb, GdUb, GdGb, FdUb, FdGb, LdUb and LdGb distributions. For each cube, the histograms and CDFs along lines-of-sight x, y and z coincide, confirming that isotropy is preserved in each box (also demonstrated by the results in Table 1, where $\sigma_{\mathcal{R}}^{\mathrm{xy}} \simeq \sigma_{\mathcal{R}}^{\mathrm{xz}} \simeq \sigma_{\mathcal{R}}^{\mathrm{yz}}$ for all simulations). We set GdGb(z) as the basis CDF and calculate its numerical difference from the CDFs of the rest of the models. The CDFs at every line-of-sight are almost indistinguishable in each case of GdGb, UdUb*, UdUb, UdGb and GdUb, as shown by the tiny fluctuations in the zero line (Fig. 4). The CDFs of FdUb, FdGb, LdUb and LdGb deviate significantly from the basis CDF.

Using the numerical CDF curves, we perform a Kolmogorov-Smirnov (KS) test with the null hypothesis being that the two RM samples, observed either in the x, y or z direction, are drawn from the same distribution. The KS test is non-parametric and reports the maximum value of absolute (vertical) difference between two CDFs (see e.g. Press et al. 2007). We calculate the KS statistics which are summarised in Table 2. We obtain $D \ll 1$ and p-value probabilities in the range of $0.2 - 0.6$, favouring the null hypothesis since $p > 0.05$. Our KS tests do not show evidence of anisotropy.

In addition, we consider a fractal medium with two density phases (hereafter referred to as cloudy models), mimicking the typical environments in the ICM/ISM (see Appendix B). We consider various cloud volume filling factors $f = 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}$, and 10^{-6}, corresponding to Cd2, Cd3, Cd4, Cd5 and Cd6, respectively. Figs. 5 and 6 show the $\log_{10}$ cross-sections and column densities of Cd3 and Cd5, respectively. The cross-sections are a slice taken from the cloudy models Cd3 and Cd5 at $x = 128$, $y = 128$ and $z = 128$. The cross-sections and column densities show the non-uniformity of the diffuse media and the cloud phases. The cloudy models are fairly isotropic along every line-of-sight, with Cd3 being more dense than Cd5, as indicated by the larger number of bright specks embedded within

the cloudy media. Fig. 7 shows that the RM maps of the Cd2Gb and Cd2Ub* distributions are indistinguishable, despite the distinction between the distributions of magnetic field strengths, especially with Ub* being non-solenoidal and unphysical. Moreover, our calculations in Table 3 show that the RMS statistics are unable to tell the cloudy features apart, in spite of Cd2 – 6 having different volume filling factors. In particular, the RMS statistics for various distributions of Cd and b are $\sigma_{\mathcal{R}} \simeq 29.3\,\mathrm{rad\,m^{-2}}$, which is similar to the RMS statistics for various distributions of our single-phase models in Table 1, indicating that the RMS method cannot distinguish between a range of different clumpy (or smooth) configurations of density and magnetic fields. We also calculate the sky-transverse standard deviations and find that, with the exception of the overcast model Cd2, the $\varsigma_{\mathcal{R}}$ decreases with decreasing volume filling factor. This is expected since the scatter should be less with fewer clouds (and we approach the L lognormal models as $f \rightarrow 0$). Clumpiness always causes $\varsigma_{\mathcal{R}} > \sigma_{\mathcal{R}}$, and often by large multiples (with relative differences up to 94%). Furthermore, comparing the dispersions between the longitudinal direction and the sky transverse direction, the cloudy models in Table 3 show a greater scatter than the Ud, Gd, Fd and Ld models did in Table 1. The variability of standard deviations may be attributed to the random shapes and orientations of the clouds.

We also calculate histograms (not shown) to characterise the RM distributions from every line-of-sight through the Cd2Ub*, Cd2Ub, Cd2Gb, Cd3Ub*, Cd3Ub, Cd3Gb, Cd4Ub*, Cd4Ub, Cd4Gb, Cd5Ub*, Cd5Ub, Cd5Gb, Cd6Ub*, Cd6Ub and Cd6Gb distributions. For each cube, the histograms along lines-of-sight x, y and z coincide, confirming that isotropy is preserved in each box, which is also shown by $\varsigma_{\mathcal{R}}^{\mathrm{xy}} \simeq \varsigma_{\mathcal{R}}^{\mathrm{xz}} \simeq \varsigma_{\mathcal{R}}^{\mathrm{yz}}$ in Table 3.

The results from the KS-tests are summarised in Table 4. The KS statistics do not show evidence of anisotropy. Using GdGb(z) as the basis CDF, we calculate its numerical difference from the CDFs of the cloudy, magnetised models in Fig. 8. These panels are almost indistinguishable between different configurations of magnetic fields, for example, the numerical difference trends for Cd3Ub*(x,y,z), Cd3Ub(x,y,z) and Cd3Gb(x,y,z) look similar to each other. This suggests that the RMs are more dependent on the cloudy structures, rather than the magnetic field configurations since the density variations are of orders of magnitude within each cube, while the dynamic variation of the magnetic field is relatively smaller. Notably the CDFs of Cd2 show the largest deviation from the basis CDF, whereas the CDFs for the rest of the models, apart from Cd3, are almost indistinguishable. This may be a consequence of a scarcity of clouds in Cd4, 5 and 6.

Hence, from our results above, the widely-used RM fluctuation formula (RMS statistics) is valid when all of the following conditions hold: (i) a random field produces random Faraday rotation, (ii) there exists a meaningful characteristic thermal electron number density, (iii) there exists a uniform or Gaussian distribution of magnetic field strengths, (iv) the field is isotropic, and (v) the density and the magnetic field are not correlated. In situations where some of these criteria are not met, the RMS statistics would be inadequate to be used to interpret the magnetic field properties from the RM analyses. Discrepancies could in principle be large in

some environments such as cluster cores where multiphase features are obvious in other wavebands (e.g. Conselice et al. 2001) or faint cluster outskirts where clumpiness is conjectured (e.g. Urban et al. 2014).

4.2 Interpreting magnetic field properties from polarisation analyses

4.2.1 Ambiguity in the polarisation angle

The inference of RM from observations of linear polarisation is subjected to an $n\pi$ ambiguity in its direction (Ruzmaikin & Sokoloff 1979). For a clean line-of-sight with a single point source, the polarisation angle φ and the wavelengths λ satisfy a relationship: $\varphi = \varphi_0 + \mathcal{R}\lambda^2$, fitting the observation for the intrinsic polarisation angle φ_0 and the slope $\mathcal{R}$ gives the rotation measure. The foreground magnetic field structure can be inferred from the RM if the emission measure is known. In practice, the measured polarisation angle φ can only be constrained between 0 and π, hence there is an ambiguity of $\pm n\pi$, where n is an integer, thus causing a problem in determining φ_0 and $\mathcal{R}$.

Early efforts were taken to resolve this ambiguity by imposing a search limit for the best RM from an astrophysical perspective and carrying out observations in several frequencies so to obtain the best fit using a chi-squared minimisation (see e.g. Simard-Normandin et al. 1981; Rand & Lyne 1994). This method assumed that no $n\pi$ ambiguity occurs between two closely-spaced wavelengths, such that $|\Delta\varphi| < \pi/2$ is fulfilled (Ruzmaikin & Sokoloff 1979). The source is observed across a radio broad band with sparsely sampled wavelengths, and near each observed wavelength, combinations of $(\varphi \pm n\pi)$ are considered in the fitting process. While this method can be applied to Faraday-thin media with a bright background point source, it sometimes gives multiple acceptable solutions. It does not work well for faint sources. In the Faraday-thick regime, the method will break down because the linear relation above does not hold. It is also problematic when there are multiple sources along a line-of-sight or when Faraday depolarisation occurs (see e.g. Vallee 1980; Sokoloff et al. 1998; Farnsworth et al. 2011).

Recently, alternative methods have been developed, for example, the circular statistical method (Sarala & Jain 2001), the PACERMAN algorithm (Dolag et al. 2005; Vogt et al. 2005), the RM synthesis/RMCLEAN method (Burn 1966; Brentjens & de Bruyn 2005; Heald et al. 2009), Stokes QU-fitting (e.g. Farnsworth et al. 2011; O'Sullivan et al. 2012), and the dependence on RM of neighbouring sources (Taylor et al. 2009; Ma et al. 2019). The $n\pi$ ambiguity is one of the obstacles that must be overcome when analysing large-scale magnetic fields using the RM information. On the other hand, we may bypass our reliance on the RM statistics by carrying out a proper (covariant) polarised radiative transfer, which can directly track the evolution of polarisation along a line-of-sight to resolve the $n\pi$ ambiguity without having to make an a priori assumption on the Faraday complexity (see Chan et al. 2019).

4.2.2 Issues in analyses of polarisation associated with large-scale astrophysical structures

FRBs and quasars as diagnostics:
FRBs and quasars are exceptionally bright, polarised radio sources, observable across cosmological distances. They are therefore useful probes of the intergalactic magnetic fields (see e.g. Xu & Han 2014b; Zheng et al. 2014; Akahori et al. 2016; Ravi et al. 2016; Vazza et al. 2018; Hackstein et al. 2019) and their evolution (see e.g. Xu & Han 2014b), if their redshifts and dispersion measures are known (see e.g. Kronberg & Perry 1982; Blasi et al. 1999; Kronberg et al. 2008; Xu & Han 2014a; Petroff et al. 2016). Circular polarisation was detected in some quasars (see e.g. Roberts et al. 1975; Saikia & Salter 1988; Rayner et al. 2000; O'Sullivan et al. 2013) and FRBs (see e.g. Petroff et al. 2015, 2017), indicating that Faraday conversion (see e.g. Vedantham & Ravi 2019; Gruzinov & Levin 2019) or scintillation-induced variations (Macquart & Melrose 2000) might occur. As the number of detections of FRBs and quasars increases (see e.g. Keane 2018), the polarisation properties of their signals can be used to better constrain large-scale magnetic field properties. Apart from the effects of Faraday conversion and scintillation, it is also important to distinguish between the RM contributions from multiple sources along the line-of-sight, consider the effects of traversing multi-phase media, as well as taking into account of the structural evolution and stretching of radiation wavelength in an expanding Universe (see e.g. Han 2017). In these situations, RM is no longer sufficient to fully characterise the changes in polarisation and hence a covariant cosmological polarised radiative transfer treatment is necessary (see Chan et al. 2019).

Direct radio emission from large-scale structure:
An emissive and Faraday-rotating medium will result in a net depolarisation due to differential Faraday rotation (e.g. Sokoloff et al. 1998; Beck 1999; Shukurov & Berkhuijsen 2003; Fletcher & Shukurov 2006). This effect is particularly important in extended sources such as emitting filaments in the cosmic web. A simple Faraday screen with a bright source behind a Faraday-rotating medium would be insufficient to capture this effect properly. A covariant polarised radiative transfer calculation is therefore essential to evaluate the line-of-sight depolarisation effect from all radiation processes at different redshifts (see Chan et al. 2019).

Contamination in the power spectrum:
The power spectrum of the observed polarised intensity may be contaminated by emissions from the medium and embedded sources. Contributions from these sources would lead to apparent higher power in fluctuations at small-scales. It is important to assess whether these signatures due to spatially separated sources can be distinguished from those imparted due to the true structures of magnetic fields. In addition to these, the interpretation of the power spectrum is complicated by the contributions at various cosmological redshifts. Consider a radio observation of the sky at a fixed frequency $\nu_{\rm obs}$. The observed power spectrum P_k is the result of contributions from sources at different redshifts. Hence, at each k, the power spectrum is contaminated by different levels of emission from various sources at higher redshifts (see Fig. 9), which differ from the power spectrum of the Universe at every redshift, $P(k)|_z$. Local $P(k)|_z$ does not contain any con-

RM (rad m^{-2})

Table 1. The dispersion of RM, $\sigma_{\mathcal{R}}^{xy}$, $\sigma_{\mathcal{R}}^{xz}$ and $\sigma_{\mathcal{R}}^{yz}$, calculated along lines-of-sight z, y, and x, respectively, as light travels through various configurations of magnetised, thermal plasma. The transverse dispersion is calculated from the RM maps over the sky plane: $\varsigma_{\mathcal{R}}^{xy}$, $\varsigma_{\mathcal{R}}^{xz}$ and $\varsigma_{\mathcal{R}}^{yz}$. The last three columns show the ratios of the longitudinal dispersion to the transverse dispersion. The realisations are normalised to the order of magnitude typically found in galaxy clusters: $\langle n_{e,th} \rangle \sim 10^{-3}\,\mathrm{cm}^{-3}$, $B_{rms} \sim 1\,\mu\mathrm{G}$ and $L \sim 1\,\mathrm{Mpc}$. The magnetic fields are strictly divergence-free, except for Ub*.

tribution from the higher redshifts, whereas observationally, different components at higher k are picked up at ν_{obs}.

5 CONCLUSIONS

Faraday rotation measure fluctuation (RMF) analysis at radio wavelengths is considered as a diagnostic tool for cosmic magnetism. Most of the current methods in RMF analyses rely on a random-walk model in which the standard deviation of RMF provides a statistical measure of the field correlation length. Our objective is to assess the validity of the conventional random walk method as a cosmic magnetic field probe. We simulate various configurations of density and magnetic field fluctuations in astrophysical plasmas to calculate the dispersion of RM. We calculate and compare
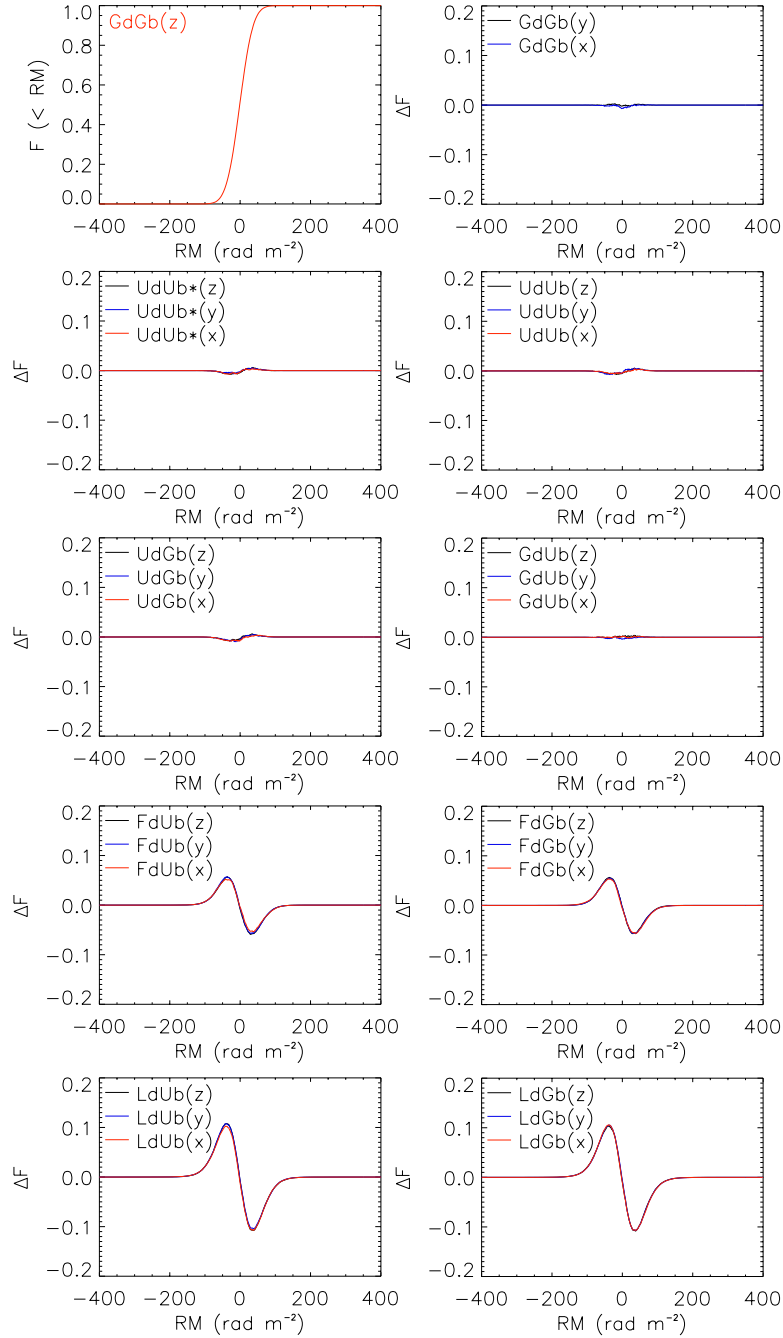

Figure 4. Top-left panel showing the CDF of GdGb(z) as a reference to calculate the numerical differences with the CDFs of GdGb(y), GdGb(x) as well as UdUb*, UdUb, UdGb, GdUb, FdUb, FdGb, LdUb and LdGb for every line-of-sight. The CDFs are almost identical in all cases, except for models with fractal and log-normal density distributions.

the line-of-sight longitudinal dispersion with the sky transverse dispersion.

Our results are as follows: (i) Numerically, the divergence filtering also creates a residual dipole, as a result of IDL's preferential direction in its Fourier transform function. This can be removed by taking a linear superposition of three orthogonal field realisations. (ii) The conventional random walk model applies in some but not all astrophysical situations. More specifically, it is valid when the density fluc-

tuations are uniformly-distributed or Gaussian-distributed. The model breaks down for densities with fractal and log-normal structures. (iii) Density fluctuations can obscure the effect of magnetic field fluctuations, and therefore affect the correlation length of magnetic fields determined by the conventional random walk model. Our results show that it is difficult to disentangle the signals from density and field fluctuations based on the value of the standard deviation of the RM, $\sigma_{\mathcal{R}}$, itself. More specifically, our demonstration

Figure 6. Column densities of Cd3 (top) and Cd5 (bottom) in the x (left), y (middle) and z (right) directions.

models show that different statistical indicators can potentially mislead, $\sigma_{\mathcal{R}} < \varsigma_{\mathcal{R}}$, by tens of percents or by factors of a few (if there is unrecognised cloudiness).

Even without degeneracy between the signals from density and field fluctuations, radiative processes such as absorption and emission can confuse and ambiguate the interpretation of the RM. Moreover, in addition to the thermal electrons, non-thermal electrons can also contribute to the Faraday rotation. We conclude that the random walk approach is not universally valid and a more proper treatment based on (covariant) polarised radiative transfer in spatially detailed models is necessary to develop solid theoretical models and predictions in preparation for the SKA.

APPENDIX A: DIVERGENCE-FREE FILTER FOR THE MAGNETIC FIELD

Consider a vector $\boldsymbol{k}$ ($= k_i$), defining a reference axis in a vector space. Any other arbitrary vector $\boldsymbol{X}$ can be decomposed into two components, one parallel to and another one perpendicular to $\boldsymbol{k}$: $\boldsymbol{X} = \boldsymbol{X}_{\parallel}^{(k)} + \boldsymbol{X}_{\perp}^{(k)}$, with $\left| \boldsymbol{k} \cdot \boldsymbol{X}_{\parallel}^{(k)} \right| \geq 0$ and $\boldsymbol{k} \cdot \boldsymbol{X}_{\perp}^{(k)} = 0$. Now introduce a projection operator $\mathcal{P}(\boldsymbol{k})$, such that, $\boldsymbol{X}' = \mathcal{P}(\boldsymbol{k}) \, \boldsymbol{X} = \boldsymbol{X}_{\perp}^{(k)}$. This projection operator eliminates the longitudinal component of $\boldsymbol{X}$, ensuring that $\boldsymbol{k} \cdot \boldsymbol{X}' = 0$ for any given $\boldsymbol{X}$. A non-trivial example of $\mathcal{P}(\boldsymbol{k})$ is $(\boldsymbol{I} - \hat{\boldsymbol{k}}\hat{\boldsymbol{k}})$, where $\boldsymbol{I}$ is an identity operator and $\hat{\boldsymbol{k}} = \boldsymbol{k}/|\boldsymbol{k}|$, such that,

$$\boldsymbol{k} \cdot \left[\left(\boldsymbol{I} - \hat{\boldsymbol{k}}\hat{\boldsymbol{k}} \right) \cdot \boldsymbol{X} \right] \;=\; k_i \left(\delta_{ij} - \frac{k_i k_j}{k^2} \right) X_j \;=\; 0 \,. \tag{A1}$$

Magnetic fields in vacuum are solenoidal, i.e. divergence-free, satisfying $\nabla \cdot \boldsymbol{B} = \partial_i B_i = 0$. In Fourier space, the divergence-free relation is expressed as $\boldsymbol{k} \cdot \boldsymbol{B}(\boldsymbol{k}) = k_i B_i = 0$, which requires that the field component parallel to $\boldsymbol{k}$ must vanish. Thus, we may apply the filter $(\boldsymbol{I} - \hat{\boldsymbol{k}}\hat{\boldsymbol{k}})$ in Fourier space to prepare a divergence-free magnetic field (with designated structural properties) from a generic initial simulated random vector field (with otherwise the same structural properties). The procedures are as follows:

(i) Construct a random field $\tilde{\boldsymbol{B}}(\boldsymbol{k})(= \tilde{B}_i(k_m))$ according to the specified structural properties in Fourier space.

(ii) Apply the divergence-free filter, i.e. carry out the projection operation: $B_i(k_m) = (\delta_{ij} - k_i k_j/k^2)\tilde{B}_j(k_m)$.

(iii) Use an inverse-Fourier transform on $B_i(k_m)$ to obtain $B_i(x_m)$ in configuration space.

As the filtering process removes the longitudinal part of the magnetic field in Fourier space, it reduces the total magnetic energy stored in the system. The Parseval's (energy) Theorem,

$$\int_{V_x} d^3\boldsymbol{x} \, |\boldsymbol{B}(\boldsymbol{x})|^2 = \int_{V_k} d^3\boldsymbol{k} \, |\boldsymbol{B}(\boldsymbol{k})|^2 , \qquad (A2)$$

requires that the total magnetic energy is reduced by the same amount in configuration space as in Fourier space. With the divergence-free magnetic field given by $\boldsymbol{B}(\boldsymbol{k}) = (\boldsymbol{I} - \hat{\boldsymbol{k}}\hat{\boldsymbol{k}})\tilde{\boldsymbol{B}}(\boldsymbol{k})$, the energy density of the magnetic field is

$$\frac{1}{8\pi}\,|\boldsymbol{B}|^2 = \frac{1}{8\pi}\left[\left(\delta_{ij} - \frac{k_i k_j}{k^2}\right)\left(\delta_{im} - \frac{k_i k_m}{k^2}\right)\tilde{B}_j \tilde{B}_m\right]$$
$$= \frac{1}{8\pi}\left[\tilde{B}_i \tilde{B}_i - \frac{1}{k^2}\left(k_i \tilde{B}_i\right)^2\right]$$
$$= \frac{1}{8\pi}\,|\tilde{\boldsymbol{B}}|^2\,(1 - \mu^2) , \qquad (A3)$$

where $\mu = \hat{\boldsymbol{k}} \cdot \tilde{\boldsymbol{B}}/|\tilde{\boldsymbol{B}}|$. For a randomly-oriented magnetic field in Fourier space,

$$\langle 1 - \mu^2\rangle = \frac{1}{2}\int_{-1}^{1} d\mu \, \left(1 - \mu^2\right) = \frac{2}{3} . \qquad (A4)$$

Hence, one-third of the magnetic energy density is filtered out. This is the expected amount when there is equipartition between the energies in the longitudinal component and the two orthogonal perpendicular components (the solenoidal components) of the initial "magnetic" field $\tilde{\boldsymbol{B}}$. To recover the energy loss in the divergence-free filtering process, we may renormalise the resulting divergence-free magnetic field, either in configuration space or in Fourier space, by a multiplicative factor $\sqrt{3/2}$.

APPENDIX B: PREPARATION OF THE MODEL 2-PHASE FRACTAL CLOUDS

Starting from even the most minute inhomogeneities, astrophysical plasmas are susceptible to form substructures through a variety of thermal, magnetic, and buoyancy instabilities (e.g. Field 1965; Shu et al. 1972; Balbus & Soker 1989; Quataert 2008; McCourt et al. 2012; Sharma et al. 2012; Wareing et al. 2016). An optically thin plasma of nearly solar composition has a temperature-dependent radiative cooling function that incurs thermal instability over an interval $10^4\,\mathrm{K} \lesssim T \lesssim 10^7\,\mathrm{K}$. An initially homogeneous medium can spontaneously self-segregate into a quasi-equilibrium of two coexisting phases: the original hot diffuse medium; and a minor component of cooler dense clouds. Externally imposed isobaric conditions imply a density ratio $\gtrsim 10^3$ between the phases, in the absence of any further gravitational collapse. Thermally condensed clouds are endemic in otherwise hot extragalactic media, and can stretch into filaments in up-flows and downflows associated with active galaxies (e.g. Ford & Butcher 1979; Saxton et al. 2001; Conselice et al.

model	$\log f$	m_c/M	a_x/A	a_y/A	a_z/A
Cd2	-2.01	0.912	0.713	0.752	0.749
Cd3	-3.01	0.495	0.150	0.155	0.155
Cd4	-4.02	0.0877	0.0188	0.0190	0.0189
Cd5	-5.12	0.00746	0.00171	0.00172	0.00169
Cd6	-6.32	0.000477	0.000122	0.000122	0.000122

Table B1. Summary of cloudy model properties: volume filling factors f; cloud mass fraction; area covering factors for the three orthogonal views. Before radiative transfer calculations, all models are normalised to the same total mass or mean density.

2001; McDonald et al. 2010; Voit et al. 2017; Combes 2018; Olivares et al. 2019).

As a test of RMF due to strong density inhomogeneities, we build two-phase toy models capable of approximating the knotty medium of a galaxy cluster core, or the ISM of an elliptical galaxy that acquired clouds (either via thermal instability or a wet-dry merger). Initially we generate a Gaussian distribution of pseudo-random complex numbers, and apply an amplitude filter to obtain a Kolmogorov-like power spectrum. This cube is transformed according to the Elmegreen recipe for imitating lognormal density fluctuations in a turbulent medium, which will represent the diffuse phase. We prescribe a volume filling factor of clouds $(0 < f \ll 1)$ and select the densest ranked voxels, down to a suitable threshold. Their densities are multiplied by a uniform constant, set to ensure a mean density ratio of 10^3 between the cloud and non-cloud phases. Assuming that the clouds are condensing from the hot medium, we normalise the mean of the entire cloudy block to $10^{-3}\,\mathrm{cm}^{-3}$, matching the standard for our single-phase density models.

We create and test models ranging from a negligible smattering of clouds $(f \approx 10^{-6})$ to a heavily obscured over-cast case $(f \approx 10^{-2})$ where a majority $(\gtrsim 0.7)$ of RM map pixels or rays traverse at least one dense cloud. Table B1 presents basic global properties of these models. In area terms, the cloud coverage factors decrease with f, and vary with orientation due to the clouds' random fractal shapes. Clouds account for only a tiny fraction of the total mass in Cd4–Cd6, or just under half the mass in Cd3. The overcast case Cd2 is dominated by the mass of the dense cold phase, making it unrealistic for the filament-infused core of a galaxy cluster (where the cold fraction is at most a few tens of percents), but perhaps more like the primordial medium of a hypothetical wet protogalaxy. The mean densities of the cubes vary by factors of a few before their normalisations into fiducial ICM units.
