16 **Abstract** In spite of the general use of diet data in ecological research, still very little is  
17 known about the relative roles of spatial, temporal and biotic (e.g. taxonomic identity, size,  
18 sex) factors in dietary variability of fishes. Here, we applied canonical correspondence  
19 analysis and variation partitioning to examine the roles of taxonomic, annual, seasonal, lake  
20 basin, habitat and ontogenetic (standard length,  $L_S$ ) factors in the dietary variation of fishes in  
21 large and shallow Lake Balaton, Hungary. The analyses were performed at the assemblage  
22 (15 fish species) and the individual species levels, and based on high (24 fine resource  
23 categories) and low resolution (nine broad resource categories) diet data. As hypothesized,  
24 most of the explained variation related to interspecific differences, while the roles of sampling  
25 year, season, lake area, habitat and  $L_S$  proved to be unexpectedly low at the assemblage level.  
26 In addition, no regularity was found in how the relative roles of these factors change between  
27 fish species. The high ratio of the unexplained variation suggests that individual variations in  
28 foraging strategies and resource use of fishes and unascertained stochastic processes had a  
29 strong influence on dietary variability both at the assemblage and the individual species  
30 levels.

## 35 **Introduction**

36

37 Analysis of feeding relationships forms a fundamental part of ecological research. For fishes  
38 the direct analysis of the stomach (gut) content is frequently used to provide information  
39 about their food resource use, suitability of the habitat, potential biotic interactions and  
40 individual feeding strategies (e.g. Bergman, 1990; Kakareko et al., 2005; Gliwicz et al., 2006;  
41 Adámek et al., 2007; Ginter et al., 2012a). In a wider, ecosystem level context, diet data helps  
42 to more directly quantify functional composition and food web organization and in general  
43 the role of fishes in aquatic ecosystems (Power, 1990).

44 Separating the components of the dietary variation provide information about how different  
45 environmental (e.g. seasonality and habitat) and/or biological factors (i.e. any morphological,  
46 biological and behavioural traits) determine diet composition (Hovde et al., 2002; Chassot et  
47 al., 2008; Quevedo et al., 2009; Pusey et al., 2010). Diet of fishes varies due to a diversity of  
48 factors. At the assemblage level, interspecific differences in the feeding behaviour and food  
49 preference generally have predominant role in dietary variability (Piet et al., 1999; Mérona &  
50 Rankin-de-Mérona, 2004; Pusey et al., 2010). At the species level, ontogenetic changes are  
51 one of the most characteristic components of the dietary variability. For fishes, shifting  
52 between resources is one way to follow the increasing energy requirement during growth  
53 (Werner & Gilliam, 1984). Moreover, ontogenetic diet shifts decrease intraspecific  
54 competition for food between the adults and their offspring (Werner & Gilliam, 1984;  
55 Persson, 1988; Mittelbach & Persson, 1998). The diet of fishes varies considerably with time  
56 primarily due to the heterogeneity of food resources along seasonal and annual scales  
57 (Warburton et al., 1998; Mérona & Rankin-de-Mérona, 2004; Ginter et al., 2012b; Nunn et  
58 al., 2012). Diet of fish can also vary between habitat types (Vinni et al., 2000; Svanbäck &  
59 Eklöv, 2002; Platell et al., 2007) and along spatial resource gradients (Mittelbach et al., 1992;

60 Francis & Schindler, 2009). In addition, it has been shown that variations among individuals  
61 may comprise a large proportion of the population's niche breadth, especially for some species  
62 which exhibit generalized feeding at the population level (Bolnick et al., 2003; 2007). Inter-  
63 individual dietary variation has two major components. The stochastic component is related to  
64 the small-scale heterogeneity in the density and taxonomic composition of food resources.  
65 This component is responsible for the short-term individual specialization and for the  
66 observed dietary differences between individuals of a fish species that forage in the same  
67 habitat but among different resource patches (Malone & McQueen, 1983; Downes et al.,  
68 1993; Ritchie, 1998). The persistent component is related to phenotypic or behavioural  
69 differences of individuals (Bolnick et al., 2003). Finally, results of diet analyses are inherently  
70 variable because stomach or gut content provide only a snap shot picture of what a fish has  
71 been eating in a very short time period (i.e. from 1 hour to one day). In spite of the general  
72 use of diet data in ecological research, still very little is known about the relative roles spatial,  
73 temporal and biotic (e.g. taxonomic identity, size, sex) factors play in dietary variability of  
74 fishes. The few studies performed on marine (Hovde et al., 2002; Chassot et al., 2008) and  
75 tropical lotic fish species and assemblages (Pusey et al., 2010) identified low to moderate  
76 explainable proportion of dietary variation. However, to the best of our knowledge no  
77 comprehensive work has been published for temperate freshwater fish assemblages.

78 This study aims to investigate the main components of intra- and interspecific dietary  
79 variability of fishes in Lake Balaton, Hungary. Feeding ecology of fishes has been extendedly  
80 studied in Lake Balaton (Specziár & Rezsú, 2009), and by now, there is a significant data  
81 base providing a perfect opportunity for analysing dietary variability and its components.  
82 Previous investigations showed that the diet of cyprinids vary considerably between the main  
83 littoral habitats (i.e. macrophyte free zone, macrophyte covered area and ripraps – lake bank  
84 sections stabilised with rocks) due to the differences in the food resources they provide

85 (Specziár et al., 1998; Specziár, 1999). The characteristic trophic gradient along the  
86 longitudinal axis of the lake influences the diet composition of several fish species (Bíró et  
87 al., 1991; Simonian et al., 1995; Rezsú & Specziár, 2006). Seasonal differences are evident in  
88 the diet of most fish species (Bíró, 1973, 1974; Bíró et al., 1991; Simonian et al., 1995), and  
89 year-to-year changes in the abundance of some food organisms were also proved to affect the  
90 feeding of fishes (Bíró, 1973 and references therein; Bíró, 1974). Recent studies focused on  
91 ontogenetic diet patterns (Bíró et al., 1991; Bíró & Muskó, 1995; Specziár & Bíró, 2003;  
92 Specziár, 2005; Rezsú & Specziár, 2006; Specziár & Rezsú, 2009; Specziár 2011), and it was  
93 found that 13 out of the 15 fish species investigated showed marked size-related dietary  
94 changes in the lake (Specziár & Rezsú, 2009). However, it was also proved that individuals of  
95 different species do not unequivocally separate based on their diet composition (e.g. for five  
96 cyprinid species, see Fig. 4 in Specziár et al., 1997), and feeding guilds are organized from  
97 specific size groups of more than one fish species (Specziár & Rezsú, 2009). Although, the  
98 above studies provide important information about the dietary variation among fish species  
99 and along specific spatial, temporal and ontogenetic scales, the relative importance of these  
100 scales still remained unknown.

101 Particular goals of the present study were to quantify the importance of taxonomic (i.e.  
102 between species), temporal (i.e. year and season), spatial (i.e. lake basin and habitat), and  
103 ontogenetic factors in the dietary variation of fishes in Lake Balaton, and to explore how the  
104 relative importance of these factors (except the taxonomic factor) vary among fish species. It  
105 was hypothesized that (i) at the assemblage level (i.e. all fish species analysed together), the  
106 largest fraction of the total variance would be related to interspecific differences, and (ii) at  
107 the species level, the relative importance of different explanatory factors would vary markedly  
108 among species according to their taxonomic relationship and guild membership. Additionally,  
109 since ecological studies consider diet composition at variable resolution levels (i.e. taxonomic

110 level to which food items are identified), it was investigated how the observed patterns  
111 change between high (i.e. 24 fine resource categories) and low resolution (i.e. nine broad  
112 resource categories) diet composition data.

113

## 114 **Materials and methods**

115

### 116 Study area

117

118 Balaton is the largest shallow lake (surface area: 593 km<sup>2</sup>; mean depth: 3.2 m) in Central  
119 Europe, situated at 46° 42' - 47° 04' N, 17° 15' - 18° 10' E and 104.8 m above sea level. The  
120 lake is meso-eutrophic with mean annual chlorophyll-a concentrations of 3.6-18.7 mg m<sup>-3</sup>  
121 (Istvánovics et al., 2007). The lake is slightly alkaline (400 mg l<sup>-1</sup> of Ca<sup>2+</sup> and Mg<sup>2+</sup>(HCO<sub>3</sub><sup>-</sup>)<sub>2</sub>),  
122 pH ranges 8.2-9.1, and has a conductivity of 550-671 µs cm<sup>-1</sup>. In general the lake is turbid  
123 with a Secchi disc depth varying between 0.2 m and 0.8 m. Oxygen deficiency has never been  
124 registered in the lake, and concentrations of pollutants are low or insignificant. Forty-seven  
125 percents of the lake shore is covered by reed grass *Phragmites australis*. Submerged  
126 macrophytes occur sparsely in the littoral zone. Significant part of the lake shore was  
127 stabilized with stones, and these riprap habitats are covered by filamentous algae (mainly  
128 *Cladophora* spp.) and inhabited by dense invertebrate community (Muskó et al., 2007;  
129 Balogh et al., 2008). There are also several boat harbours along the lake, which provide  
130 specific habitat because they are sheltered from swash. Detailed information on the limnology  
131 and fish fauna of the lake can be found in studies of Herodek et al. (1988), Bíró (1997),  
132 Specziár et al. (2009, 2013) and Istvánovics et al. (2007).

133

### 134 Sampling

135  
136 Explanatory factors for this study were the sampling parameters. Fish samples representing  
137 wide (i.e. lifespan in most species) size ranges of 15 species (Table 1) were collected between  
138 1995 and 2007, from three seasons (spring, summer and autumn) and in three lake basins  
139 (Keszthely, Zánka and Siófok basins; Fig. 1.) along the longitudinal axis of the lake. Five  
140 habitats were distinguished as follows: 1) offshore area, sampled at >2 km distance off the  
141 nearest shore, 2) macrophyte-free inshore area, sampled at 50 to 200 m distance off the shore,  
142 3) reed grass stand, 4) riprap, sampled at 1 to 5 m distance off the shore, and 5) boat harbour  
143 (Fig. 1). Applied sampling techniques included multi-mesh gillnetting (5 to 80 mm mesh  
144 sizes), battery powered electrofishing (1 and 6 mm anode ring mesh sizes), benthic sledging  
145 (2 mm mesh size), surface trawling (2 mm mesh size) and dip netting (1 mm mesh size).  
146 Gillnets were set for half to two hours in the morning. With gillnet most fish species could be  
147 collected effectively at sizes >50 mm standard length ( $L_S$ ). Sampling of the littoral species,  
148 especially of those hiding among macrophytes or living along the ripraps (i.e. pumpkinseed  
149 sunfish *Lepomis gibbosus*, monkey goby *Neogobius fluviatilis*, perch *Perca fluviatilis* and  
150 rudd *Scardinius erythrophthalmus*) was supplemented with electrofishing using a battery  
151 powered Smith-Root 12-B POW type equipment ([www.smith-root.com](http://www.smith-root.com)) from a small rubber  
152 boat. Electrofishing proved to be an appropriate tool for catching all size-groups of littoral  
153 species, except the earliest life stages. To capture the earliest life stages ( $L_S \leq 20$  mm) of  
154 littoral species a dip net with 1 mm mesh-size was used, while the earliest life stages ( $L_S \leq 50$   
155 mm) of offshore species were captured with a benthic sledge being 1 m wide and 0.34 m high,  
156 and a framed surface trawl 1 m wide and 0.5 high. Both the benthic sledge and the framed  
157 surface trawl had a 2 mm mesh and were towed with a boat at 5.4-5.8 km h<sup>-1</sup> for 5 to 10 min.  
158 per haul.  
159

160 Diet analysis

161

162 Just after the capture, small fishes ( $L_S \leq 100$  mm) were euthanized in an overdose of tricaine  
163 methanesulfonate (MS 222;  $1.0 \text{ g l}^{-1}$ ) or clove oil ( $0.4 \text{ g l}^{-1}$ ; more recently) and then preserved  
164 in 4-10% formalin (depending on the mass of the sample). Larger specimens were instantly  
165 killed by severing the central nerve system. Then they were measured for  $L_S$  to the nearest 1  
166 mm, dissected and their stomachs or guts (in cyprinids) were also preserved in 4-10%  
167 formalin.

168 Protocol of the diet analysis was the same as described in Specziár & Rezsú (2009).

169 Samples were generally stored for few weeks before being leached in water and analysed.

170 Diet remains were removed from the stomachs or guts and analysed in the laboratory under a  
171 microscope, a stereo microscope or by eye (in large piscivores) depending on the size of the  
172 diet components. The present study is based on altogether 8756 examined guts and stomachs  
173 containing food remains (Table 1). Since the goal of the present study was to investigate  
174 components of the dietary variability of fishes, empty stomachs and guts were not considered  
175 in the analysis. Although, empty stomachs and guts could provide very useful information on  
176 resource availability of specialized predators, still their inclusion in the analysis can yield  
177 uncontrollable bias derived from the unknown feeding period of fishes. For example, it is  
178 impossible to differentiate between non-feeding periods and resource limitation from empty  
179 stomachs or guts. Food items were classified into taxonomic groups and prey  $>0.5$  mg were  
180 weighted to the nearest 0.1 mg, while in other cases their biomasses were calculated from  
181 length-weight relationships (Vuille, 1991; Kawabata & Urabe, 1998; Benke et al., 1999;  
182 Johnston & Cunjak, 1999; Specziár, 2011; Specziár, unpublished data).

183 Food items were grouped into 24 fine and nine broader resource categories to represent  
184 cases of high and low resolution diet analyses, respectively. High resolution resource

185 categories were: (1) *Dreissena polymorpha* larvae, (2) Rotatoria, (3) Copepoda, (4) Cladocera  
186 except *Leptodora kindtii*, (5) *L. kindtii*, (6) Ostracoda, (7) Oligochaeta, (8) benthic  
187 Chironomidae larvae (species which typically inhabit in or on the sediment, see also Specziár  
188 & Bíró, 1998), (9) non-benthic Chironomidae larvae (all other species), (10) Chironomidae  
189 pupae, (11) *Chelicorophium curvispinum*, (12) *Dikerogammarus* spp., (13) *Limnomysis*  
190 *benedeni*, (14) Isopoda, (15) *D. polymorpha* adults, (16) Gastropoda, (17) other soft-bodied  
191 aquatic Arthropoda (e.g. Collembola, Ephemeroptera, Odonata, Heteroptera, Coleoptera,  
192 Trichoptera, Acaridea), (18) ‘surface Arthropoda’ (including flying imagos of aquatic insects  
193 and all non-aquatic arthropods occurring in the diet of fishes), (19) diatoms, (20) filamentous  
194 (green) algae, (21) macrophytes, (22) detritus, (23) fishes, and (24) others (e.g. fish eggs and  
195 bait material used by anglers). While, low resolution resource categories were as follows:  
196 zooplankton (including high resolution categories: 1-5), soft-bodied benthic (i.e. organisms  
197 living in and on the sediment) macroinvertebrates (6-8), soft-bodied non-benthic (i.e.  
198 invertebrates using algae, macrophytes and artificial structures, concrete buildings and ripraps  
199 as substrate, and including Chironomidae pupae) macroinvertebrates (9-14, 17), molluscs (15-  
200 16), surface arthropods (18), live plant material (19-21), detritus (22), fishes (23) and others  
201 (24). Individual diet composition of fish was expressed in mass percentages based on both  
202 high and low resolution diet data. For brevity, diet composition data of the 15 fish species is  
203 not presented here, but some basic information is available in Table 1 and Appendix A.

204

205 Statistical analysis

206

207 Diet composition data and their dependence on fish species, place (i.e. lake basin and habitat)  
208 and time (i.e. year and season) of sampling, and ontogeny (i.e. fish size,  $L_S$ ) were investigated  
209 by performing canonical correspondence analysis (CCA) using CANOCO version 4.5

210 software (ter Braak & Šmilauer, 2002). Ordination techniques are widely used to investigate  
211 patterns in multivariate species-environmental data sets, especially when the distribution of  
212 data do not support the application of general linear models (e.g. multivariate analysis of  
213 variance, MANOVA) requiring samples for all possible factor state  $\times$  species combinations  
214 (Lepš & Šmilauer, 2003). The method of CCA was chosen because preliminary detrended  
215 correspondence analysis (DCA) indicated relatively long gradient length at both the  
216 assemblage and most species level data sets ( $\geq 4$  in standard deviation units; Lepš & Šmilauer,  
217 2003). The CCA analysis was performed at both the entire assemblage level (the entire  
218 database where all 15 fish species were analysed together and where the 15 fish species were  
219 included to explanatory variables) and at the level of individual fish species. The analyses  
220 were based on both the high and the low resolution diet data. Correspondingly, 32 sets of  
221 CCA analyses were performed, two (high and low diet resolution) at the assemblage level and  
222 30 (15 species  $\times$  high and low diet resolution) at the species level. Individual diet data (i.e.  
223 each fish represented a separate diet sample) were used throughout the analysis. In each  
224 analysis, rare food categories (i.e.  $< 0.5\%$  total representation or  $< 2\%$  frequency of occurrence  
225 in the concerning data set) were merged with the resource category called others. Response  
226 variables (i.e. relative diet composition data) were  $\arcsin(x^{0.5})$  transformed prior to analysis  
227 according to the most preferred method of handling proportional data ranging between 0 and  
228 1 (Podani, 2000; but see Warton & Hui, 2011). This transformation gives more weight to food  
229 items with low (i.e. with values close to 0) and high (i.e. with values close to 1) relative  
230 abundances. Of the explanatory variables, fish species (in the assemblage level analysis only),  
231 lake basin, habitat, sampling year and season were treated as categorical factors and re-coded  
232 into binary dummy variables (Lepš & Šmilauer, 2003); whereas  $L_S$  was treated as quantitative  
233 variable. Since we assumed that a unit change in the  $L_S$  has much less effect on the diet of  
234 fishes at the higher end (i.e. in adults) than at the lower end (i.e. at the early of the ontogeny)

235 of its range (e.g. see  $L_S$  intervals for identified ontogenetic species size groups in Specziár &  
236 Rezsú, 2009), the data were  $\log_{10}(x)$  transformed prior to analysis.

237 In each analysis (i.e. assemblage  $\times$  diet resolution or fish species  $\times$  diet resolution), first,  
238 a preliminary overall CCA model was built, which included all potential explanatory  
239 variables (Lepš & Šmilauer, 2003). The relative contribution of each variable to the model  
240 was assessed by using the forward stepwise selection procedure, and their significance was  
241 studied by Monte-Carlo permutation test with 9 999 permutations under the full model. On  
242 the basis of this selection procedure, only significant explanatory variables ( $P < 0.05$ ) were  
243 retained in the final CCA model. Similarly, statistical significance of ordination axes and the  
244 whole model (i.e. including all axes) were studied using the Monte-Carlo permutation test  
245 with 9 999 permutations. Next, a series of CCA and partial CCAs were conducted to partition  
246 the effects of taxonomic (i.e. fish species; only in the assemblage level analyses), temporal  
247 (year and season), spatial (lake basin and habitat) and fish size ( $L_S$ ) on diet composition  
248 (Cushman & McGarigal, 2002).

249 Relative position of fish species in a multidimensional space based on the importance of  
250 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and ontogenetic (i.e.  $L_S$ )  
251 factors in the variation of their diet composition was done using hierarchical cluster analysis  
252 (CA) and principal component analysis (PCA). Prior to analyses, variation partition data (%)  
253 extracted from diet composition matrixes were  $\arcsin(x^{0.5})$  transformed (Podani, 2000). CA  
254 was based on the unweighted-pair-group method with arithmetic mean (UPGMA) and the  
255 Euclidean distance. Significant groups of species in the cluster diagrams were identified  
256 according to the randomization method described by Jaksić & Medel (1990). This method  
257 employs a bootstrap randomization of the raw data (fish species  $\times$  variation partitions  
258 extracted from diet data) to generate a distribution of Euclidean distances reflecting the null  
259 hypothesis of no ordinate source of variation in the diet among the investigated fish species

260 (Gotelli & Graves, 1996). Data were iterated 10 000 times and their distributions were used to  
261 find the critical value of distance below which the probability of occurrence by chance is  
262 <5% (Jaksić & Medel, 1990). CA was performed in Statistica 8.0 (www.statsoft.com) while  
263 the bootstrapping procedure was done with a macro written for Excel 2010  
264 (www.office.microsoft.com). Finally, main trends in the distribution of the identified  
265 partitions of dietary variability among the 15 fish species investigated were explored with  
266 PCA in Statistica 8.0 (www.statsoft.com).

267

## 268 **Results**

269

### 270 Assemblage level variation in the diet

271

272 At the assemblage level, total identified variation (i.e. eigen value, a measure of the  
273 explanatory power of each ordination axis; Table 2) was 16.3 in the high and 6.8 in the low  
274 resolution diet data, and 20.8% and 36.9% of them could be explained, respectively. Most of  
275 the explained variation in the individual diet composition data belonged to between species  
276 differences (Fig. 2). This factor explained alone 10.3% and 18.2%, and as shared effect  
277 mainly with the sampling year and the habitat additional 3.4% and 8.0% of the total variation  
278 in the high and low resolution diet data, respectively. A moderate part of the variation was  
279 explained by spatial and temporal factors, mainly by the sampling year and the habitat, while,  
280 effect of the  $L_S$  was small.

281

### 282 Species level variation in the diet

283

284 Similarly to assemblage level patterns, total identified variation (i.e. eigen value; Table 2)  
285 was significantly lower at low (mean: 3.0; range: 1.6-5.2) than at high (mean: 6.8; range: 4.4-  
286 13.5) diet resolution for all species, and the explained proportion of the variation was higher  
287 in the low (mean: 29.3%; range: 14.3%-54.8%) than in the high (mean: 20.2%; range 13.3%-  
288 30.6%) resolution data in all species except the *S. erythrophthalmus*. However, both the  
289 portion and the source of the explained variation in the diet data varied markedly between fish  
290 species (Fig 3 and Table 2). On average, temporal factors accounted for most of the explained  
291 variation in both the high and the low resolution diet data (7.9% and 8.4% as pure and 3.9%  
292 and 6.1% as shared effect, respectively), followed by fish size ( $L_S$ ; 3.7% and 6.9% as pure and  
293 3.7% and 6.9% as shared effect, respectively) and spatial factors (3.8% and 5.6% as pure and  
294 3.3% and 6.0% as shared effect, respectively) (Fig. 3).

295 Based on the high resolution diet data, CA identified three multi-species groups and four  
296 separate species according to the importance of the investigated factors in the variation of the  
297 diet. Pikeperch *Sander lucioperca* separated from other species mainly due to the high  
298 influence of habitat and asp *Aspius aspius* due to the high proportion of shared effect of  $L_S$ .  
299 Diet of razor fish *Pelecus cultratus* and bleak *Alburnus alburnus* were relatively strongly  
300 influenced by sampling season and lake basin, while diet of *P. fluviatilis*, *S. erythrophthalmus*  
301 and ruffe *Gymnocephalus cernuus* by pure effect of  $L_S$ . The other eight species formed two  
302 less interpretable clusters (Fig. 4). Results of the PCA were highly congruent with that of the  
303 CA and supported the separation of two obligate piscivores *S. lucioperca* and *A. aspius*, and  
304 two zooplanktivores *P. cultratus* and *A. alburnus* from the other species and also from each  
305 other. The first three principal components (PC) explained 61.1% of between species  
306 variation, and PC 1 represented a gradient based on the importance of different spatial and  
307 temporal scales, PC 2 a gradient mainly based on the importance of  $L_S$  and PC 3 a gradient  
308 primarily based on season and lake basin (Fig. 5).

309 For the low resolution data the explained variation proportions were highest in fishes  
310 with marked ontogenetic resource shift (either diet or habitat), such in *A. aspius*, *G. cernuus*,  
311 *S. lucioperca*, Volga pikeperch *Sander volgensis*, *P. fluviatilis* and *L. gibbosus* (Fig. 3b and  
312 Table 2). CA identified only one cluster with six non-piscivorous, benthic species, while, the  
313 other nine species separated significantly from this cluster and from each other (Fig. 6). PC 1  
314 in the PCA represented a gradient from the planktivorous *P. cultratus* and *A. alburnus*, which  
315 are species with no marked ontogenetic habitat and diet shifts, to the piscivorous *S.*  
316 *lucioperca*, which could be characterized with a marked ontogenetic diet shift and diverse  
317 resource use. While, PC 2 correlated positively with  $L_S$  and negatively with the importance of  
318 the shared effect of lake basin and habitat, and PC 3 correlated positively with the influence  
319 of sampling year and the shared effect of temporal and habitat factors and negatively with the  
320 importance of season in dietary variability (Fig. 7).

321

## 322 **Discussion**

323

324 The present study showed that the larger part of the dietary variability observed among  
325 individuals of 15 fish species could not be explained by between species and the considered  
326 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and ontogenetic (i.e.  $L_S$ )  
327 factors. As hypothesized, most of the explained variation related to interspecific differences at  
328 the assemblage level. This result is similar to the finding of Pusey et al. (2010) who examined  
329 a tropical fish assemblage in Australia and found that species identity accounted for 31% of  
330 the total dietary variance. Although the explanatory power of their data set was twofold  
331 higher than what we found in the present study. According to the niche concept, differences  
332 between species facilitate their long term coexistence (Whittaker et al., 1973; Leibold, 1995;  
333 Piet et al., 1999), although on a short time or habitat scale, especially when one or more food

334 resources are abundant, interspecific dietary differences may decrease (Baker-Dittus, 1978;  
335 Feyrera et al., 2003). Moreover, interspecific deviations are generally weaker at the onset of  
336 larval feeding and increase with development (Nunn et al., 2007; Specziár & Rezsú, 2009),  
337 which may result in a stronger taxonomic component in the dietary variability in studies  
338 concentrating on adult fishes. Our results thus revealed that taxonomic identity provides only  
339 a very rough picture on the diet for an individual fish, because diet composition depends on  
340 individual or instantaneous feeding strategies (Ritchie, 1998; Bolnick et al., 2003; Reid et al.,  
341 2010) and also can be highly variable in both time and space (Svanbäck & Eklöv, 2002;  
342 Platell et al., 2007; Ginter et al., 2012b; Nunn et al., 2012). Note that further part of the  
343 discussion is based primarily on the results obtained from the high resolution data, using the  
344 same food item categories that were successfully used in most previous studies in Lake  
345 Balaton.

346 Many fishes reveal pronounced size-dependent trend in their diet composition (Bergman,  
347 1990; Mittelbach & Persson, 1998; Specziár & Rezsú, 2009). Recently, Specziár & Rezsú  
348 (2009) found that 13 out of the 15 fish species investigated here showed significant  
349 ontogenetic dietary changes. In the light of this, it is a bit surprising that the proportion of  
350 mean variation explained by the  $L_S$  was low in the present study. However, the relative  
351 importance of  $L_S$  was high in some species (e.g. *P. fluviatilis*, *G. cernuus*, *S.*  
352 *erythrophthalmus*, *A. aspius*), at least compared with the importance of temporal and spatial  
353 factors. Conversely, in some typical ontogenetic diet switchers (e.g. *S. lucioperca*, *S.*  
354 *volgensis*, *L. gibbosus*), influence of temporal (i.e. year and season) and spatial (i.e. lake basin  
355 and habitat) factors on dietary variability exceeded that of the  $L_S$ , suggesting a versatile  
356 feeding behaviour in these species. In addition,  $L_S$  is closely correlated with season in younger  
357 age classes (most evidently in 0+ and 1+ age classes) and the habitat use of some fish species  
358 is also size-specific (Table 1), and therefore, part of the variance related to ontogenetic

359 changes were shared with the effect of these (i.e. season and habitat) factors. For example,  
360 these shared effects were important in three typical ontogenetic diet switchers, *A. aspius*, *S.*  
361 *luciperca* and *S. volgensis*, and accounted for 7.5% to 9.7% of the dietary variation.  
362 Discrepancy between the results of Specziár & Rezsú (2009) and the present study may also  
363 be due to the difference in the study question and the statistical approach used. Specziár &  
364 Rezsú (2009) concentrated only on ontogenetic patterns in the diet of 15 fish species and used  
365 cluster analysis based on average data of each species size group. That approach characterized  
366 trends of ontogenetic dietary changes at the population level in the 15 fish species, but  
367 without estimating their significances compared to other factors. In turn, the direct ordination  
368 method (CCA) used in the present study retained among individual variance as well, and  
369 quantified the relative importance of temporal (i.e. year and season), spatial (i.e. lake basin  
370 and habitat) and ontogenetic (i.e.  $L_S$ ) factors in dietary variability for the 15 fish species.

371 The role of sampling year was evident in most fish species suggesting that the quality and  
372 quantity of the food resource can significantly vary between years in Lake Balaton. This  
373 finding is in accordance with the results of previous studies on the temporal dynamics of  
374 several invertebrate groups, including zooplankton (G.-Tóth et al., 2011), benthic  
375 chironomids (Specziár & Vörös, 2001), littoral molluscs (Balogh et al., 2008) and amphipods  
376 (Muskó et al., 2007).

377 Season and lake basin accounted for >3% of the dietary variability only for *A. alburnus*  
378 and *P. cultratus*, both of which are offshore living, non-benthic planktivores. These species  
379 consume mainly zooplankton and periodically the swarming imagos of chironomids.

380 Availability of chironomid imagos, in turn, varies primarily between seasons and basins  
381 (Specziár & Vörös, 2001; Specziár, 2008). In shared effect with predator  $L_S$ , lake basin also  
382 influenced the diet of *A. aspius* and *L. gibbosus*, indicating that the response of these species  
383 to the trophic gradient (i.e. between basins) was size-dependent. While, considerable joint

384 effect of  $L_S$  and temporal factors suggested some size-dependent temporal variability in the  
385 diet ontogeny of *S. lucioperca*, *A. aspius* and common bream *Abramis brama*.

386 It is interesting that the habitat itself affected only weakly the diet composition of most  
387 fish species, given that there are numerous examples that show how between habitat  
388 differences in food resource can significantly influence the diet of fishes (e.g. Mittelbach et  
389 al., 1992; Vinni et al., 2000; Svanbäck & Eklöv, 2002). For example, Platell et al. (2007)  
390 found that in yellowfin seabream *Acanthopagrus latus* dietary differences were related more  
391 to the habitat than to the season and fish size. In Lake Balaton, both the diversity and the  
392 abundance of potential food resources vary significantly among habitats. This difference is  
393 most pronounced between the offshore and the littoral areas, the former characterised by  
394 highly homogeneous planktonic (G.-Tóth et al., 2011) and benthic chironomid (Specziár &  
395 Vörös, 2001) food resources, whereas the four littoral habitats (i.e. macrophyte-free inshore  
396 zone, reed grass stand, riprap and boat harbour) with more abundant and diverse food  
397 resources including also molluscs, amphipods, isopods and macrophytes (Muskó, 1990;  
398 Specziár & Bíró, 1998; Muskó et al., 2007; Balogh et al., 2008). In Lake Balaton, the highest  
399 habitat effect was found in *S. lucioperca*. Juveniles of *S. lucioperca* fed on different food  
400 resource in the offshore (dominantly *Leptodora kindtii*) than in the littoral zone (dominantly  
401 *Limnomysis benedeni*). Previous studies showed that the diet of five abundant cyprinids (i.e.  
402 roach *Rutilus rutilus*, *A. brama*, white bream *Blicca bjoerkna*, gibel *Carassius gibelio* and  
403 common carp *Cyprinus carpio*) differed between the main habitats of the littoral zone in Lake  
404 Balaton (Specziár et al., 1998; Specziár, 1999). Why the habitat seemed to be relatively  
405 unimportant in the present study could be explained by at least three reasons. Most fish  
406 species did not occur in all habitats sampled (Table 1), and their habitat choice likely included  
407 a filtering for available food resources as well. Therefore, species-specific habitat use resulted  
408 in some overlap (i.e. shared effect) between the dietary variance related to taxonomic and

409 habitat factors. Second, in some fish species ontogenetic diet shift is coupled with a habitat  
410 shift that could result in a shared effect between the  $L_S$  and the habitat factors. Third, the  
411 relatively weak effect of the habitat may also suggest that the investigated fishes have highly  
412 similar ranges of food preferences and feeding strategies over their habitats at both the species  
413 and the individual levels.

414 As showed above, a significant amount of the explained variance could be related to two  
415 or more explanatory factors. Overall, the relatively high importance of shared factor effects in  
416 the dietary variability indicated the presence of complex processes, such as species- and size-  
417 specific habitat choice, seasonality of the presence of the earliest life stages, coupled  
418 ontogenetic diet and habitat shifts, between habitats differences in the diet ontogeny and  
419 likely several other phenomenon which are hard to disentangle based purely on field  
420 observations.

421 Unexplained variation in the diet composition data was high at both the assemblage and  
422 the species levels suggesting that unmeasured factors also contributed to the observed  
423 patterns. Explainable variance was similarly low in individual diet data of Northeast Arctic  
424 Greenland halibut, *Reinhardtius hippoglossoides* (Walbaum) (Hovde et al., 2002) and in  
425 Celtic Sea fish predators (Chassot et al., 2008), but bit higher in the fish assemblage of a  
426 tropical Australian river (Pusey et al., 2010). In field datasets, it is usual that a large  
427 proportion of the variation remains unexplained due to the presence of unidentified effects  
428 and/or factors (including stochastic) which are hard to quantify. In this case, for example,  
429 within season changes were not discriminated. Further, the present study concentrated on  
430 factors affecting dietary variability primarily at the group level (i.e. species, species size  
431 groups or guilds), while individual level effects were not (practically, could not be)  
432 discriminated. The importance of individual feeding strategies has been recognized in many  
433 animal taxa including fish (Bolnick et al., 2003; Quevedo et al., 2009; Smith et al, 2011).

434 Considering the high proportion of the unexplained variation in the diet data, it is likely that  
435 individual level processes could be important in the present study as well.

436 Heterogeneous (patchy) food resource (Luo et al., 1996; Lehtiniemi et al., 2007) and/or  
437 temporal search image (Werner et al., 1981) may result in temporal individual specialization  
438 in fishes. For example, observations of Specziár (1999) showed that there is a marked duality  
439 in the feeding strategy of individual *R. rutilus*, especially in the littoral zone, where they  
440 exhibited short-term specialization either for molluscs or filamentous algae. Temporality of  
441 this specialization could be proved by that in some individuals the first part of the gut  
442 contained only one, while the second part of the gut only the other of the above food items.  
443 Temporal individual specialization is sometimes highly stochastic; the diet of individual fish  
444 foraging for unevenly distributing food resource is strongly influenced by the stochastic order  
445 different food items are encountered (Luo et al., 1996; Lehtiniemi et al., 2007). Similarly,  
446 water turbidity in shallow Lake Balaton changes stochastically in space and time (Herodek et  
447 al., 1988) that contributes to variability of prey encounter rate, and therefore, the prey  
448 selectivity of fishes (Shoup & Wahl, 2009; Carter et al., 2010).

449 Another type of individual specialization is when individuals of a species persistently  
450 differ in their feeding strategy due to consistence in phenotypic and behavioural variability  
451 (Bolnick et al, 2003; Quevedo et al., 2009; Reid et al., 2010; Kim et al., 2012). For example,  
452 persistence individual differences can be observed in 0+ *S. lucioperca*. This fish species may  
453 reveal an ontogenetic shift during the first growing season from zooplankton either to  
454 macroinvertebrates (i.e. *L. kindtii* in the offshore and *L. benedeni* in the inshore habitats) or  
455 straight to fish prey (Specziár, 2005). Such individual deviations in the timing of ontogenetic  
456 diet switching were described for other species as well (Post, 2003).

457 The present study showed that due to the high intraspecific dietary variation the total  
458 dietary niche ranges of the 15 fish species considerably overlapped in Lake Balaton. This

459 finding supports recent arguments that modelling of population level processes should  
460 consider individual level variation of organism functioning (Bolnick et al., 2003). However,  
461 the effects of short-term (including stochastic processes) and persistence individual  
462 differences in the feeding strategy, unfortunately, cannot really be separated in large-scale  
463 field studies, and can only be limitedly addressed by stable isotopic analysis, specific  
464 experiments and modelling. High individual variability in resource use should have a  
465 significant effect on intra- and interspecific resource partitioning and also on individual level  
466 growth rate and survival of fish that, in turn, influence population and community level  
467 processes. Moreover, high individual variability and wide niche breath at the population level  
468 support the adaptive generalization in the investigated fishes (Bolnick et al, 2003). Future  
469 studies should thus concentrate on quantifying the importance of individual level variations  
470 on the population's niche breath and total dietary variability, and their influence on population  
471 and community level interactions.

472       One would suppose some regularity in how the relative role of different factors  
473 influencing dietary variability change between fish species, but the present study could not  
474 identify any general pattern. CA and PCA did not show any consequent grouping of fish  
475 species neither based on their taxonomic relationships nor on their feeding mode, maximum  
476 size or any evident ecological traits. Since most species belong to more than one feeding  
477 guilds during their life-span (Specziár & Rezsú, 2009), it is likely that such patterns, if exist,  
478 might be organized rather based on species size groups than on species. Moreover, since most  
479 fish species show high plasticity in their resource use, these patterns probably also vary  
480 between habitats and in time.

481       Similarly to the findings of Chassot et al. (2008), we showed that data resolution  
482 influenced the amount of the dietary variability detected. Both the total variation identified  
483 and the proportion of variation explained differed between the high and low resolution diet

484 composition data. Lower detected variability indicates that food resource use of fishes is  
485 relatively stable at the level of broad compared to fine resource categories. Results also  
486 suggest that individual feeding strategies (both the short-term and the persistent variations)  
487 differentiate mainly at the fine resource scale. How the proportion of the explained variation  
488 changes with diet resolution likely also depends on the nature of the explanatory factors  
489 considered, and supposedly follows a bump shape pattern (i.e. it will be highest at a specific  
490 level of diet resolution). When the resolution of the diet categories is too low, important  
491 relationships may remain hidden. Conversely, when the precision of the diet analysis  
492 significantly exceeds the analytical limit of the sampling design, the high amount of the  
493 unexplainable variance might be confusing. It is suggested thus that the optimal level of diet  
494 resolution (i.e. taxonomic composition or size distribution) applied in particular studies  
495 should be set to the descriptive power of the explanatory variables investigated.

496 In conclusion, this study showed that taxonomic (i.e. between species), temporal (i.e. year  
497 and season), spatial (i.e. lake basin and habitat) and ontogenetic factors (i.e.  $L_S$ ) explained  
498 only a moderate part of the total dietary variability of fishes in a large and shallow lake  
499 ecosystem. Moreover, no regularity was found in how the relative roles of these factors  
500 change between fish species. Considering the high ratio of the unexplained variation, it is  
501 likely that short-term and persistence variations in individual foraging strategies and resource  
502 use of fishes and unascertained stochastic processes had a strong influence on dietary  
503 variability.

504

505 **Acknowledgements** We are grateful to G. Dobos for his indispensable assistance in the  
506 fieldwork and for E. T. Rezsú for processing part of the diet samples. The study was  
507 supported by grants from the Hungarian Scientific Research Fund (OTKA K 104279 and

508 OTKA CNK 80140). The work of T. Erős was supported by the Bolyai János fellowship of  
509 the Hungarian Academy of Sciences.

level data																

724 d.f.<sub>num.</sub>, degrees of freedom of the numerator; d.f.<sub>den.</sub>, degrees of freedom of the denominator. Note, that CANACO version 4.5 software do not list  
725 degrees of freedom data, these were calculated independently according to Legendre et al. (2011).  
726 \* denotes significant differences between species level eigen values and explained variation proportions between the high and the low diet  
727 resolution data according to the Student *t*-test at  $P < 0.05$ .

728 **Figure captions**

729

730 **Fig. 1** Distribution of sampling sites in Lake Balaton, Hungary. ○, offshore sites; ○, inshore  
731 macrophyte-free sites; △, reed-grass stands; □ boat harbours and ripraps

732

733 **Fig. 2** Result of the variation partitioning of the influence of taxonomic, temporal (i.e. year  
734 and season), spatial (i.e. lake basin and habitat) and ontogenetic (i.e. standard length,  
735  $L_S$ ) factors on the diet of fishes at the assemblage level (i.e. all 15 fish species  
736 examined together) in Lake Balaton, Hungary, at high (a) and low (b) diet resolution.  
737 The area of each rectangular cell is proportional to the variance accounted for by that  
738 component. The total explained variance proportion was 20.8% for the high and  
739 36.9% for the low diet resolution data. Note that variance partitions <0.5% are not  
740 specified on the figure.

741

742 **Fig. 3** Result of the variation partitioning of the influence of temporal (i.e. year and season),  
743 spatial (i.e. lake basin and habitat) and ontogenetic (i.e. standard length,  $L_S$ ) factors on  
744 the diet of 15 fish species in Lake Balaton, Hungary, at high (a) and low (b) diet  
745 resolution. ■, year; ■, season; ■, year × season (shared effect); ■, basin; ■, habitat; ■,  
746 basin × habitat; ■, size (i.e.  $L_S$ ); ■, temporal × spatial; ■, temporal × size; ■, spatial ×  
747 size; ■, temporal × spatial × size

748

749 **Fig. 4** Unweighted-pair-group clustering of 15 fish species based on the importance of  
750 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and size (i.e.  $L_S$ )  
751 related factors in their dietary variability at high diet resolution in Lake Balaton,  
752 Hungary. Broken line at 53.3% distance indicates the existence of seven clusters at  $P <$

753 0.05 probability level based on the bootstrap method of Jaksic & Medel (1990).

754 Explanatory variable groups separating the particular dendrogram branch are indicated

755

756 **Fig. 5** Principal component (PC) analysis plots of 15 fish species based on the importance of

757 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and size (i.e.  $L_S$ )

758 related factors in their dietary variability in Lake Balaton, Hungary, at high diet

759 resolution along PC 1 and PC 2 (a) and PC 1 and PC 3 (b). Score of each fish species is

760 indicated by a pictogram (explained in the down right corner of the figure) showing the

761 pure (dark grey) and shared (light grey) influences of year, season, lake basin, habitat

762 and  $L_S$  on dietary variability. Percentage variances represented by PCs are shown in

763 parentheses after the axis name. Arrows indicate the characteristic gradients represented

764 by the axes based on the significant ( $P < 0.05$ ) factor correlations ( $r$ ; given in

765 parentheses)

766

767 **Fig. 6** Unweighted-pair-group clustering of 15 fish species based on the importance of

768 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and size (i.e.  $L_S$ )

769 related factors in their dietary variability at low diet resolution in Lake Balaton,

770 Hungary. Broken line at 28.4% distance indicates the existence of 10 clusters at  $P <$

771 0.05 probability level based on the bootstrap method of Jaksic & Medel (1990).

772 Explanatory variable groups separating the particular dendrogram branch are indicated

773

774 **Fig. 7** Principal component (PC) analysis plots of 15 fish species based on the importance of

775 temporal (i.e. year and season), spatial (i.e. lake basin and habitat) and size (i.e.  $L_S$ )

776 related factors in their dietary variability in Lake Balaton, Hungary, at low diet

777 resolution along PC 1 and PC 2 (a) and PC 1 and PC 3 (b). Score of each fish species is

778 indicated by a pictogram (explained in the down right corner of the figure) showing the  
779 pure (dark grey) and shared (light grey) influences of year, season, lake basin, habitat  
780 and  $L_S$  on dietary variability. Percentage variances represented by PCs are shown in  
781 parentheses after the axis name. Arrows indicate the characteristic gradients represented  
782 by the axes based on the significant ( $P < 0.05$ ) factor correlations ( $r$ ; given in  
783 parentheses)
