## ABSTRACT

We have measured the orbital parameters of seven close binaries, including six new objects, in a radial velocity survey of 38 objects comprising a hot subdwarf star with orbital periods ranging from  $\sim 0.17$  to 3 d. One new system, GALEX J2205–3141, shows reflection on a M dwarf companion. Three other objects show significant short-period variations, but their orbital parameters could not be constrained. Two systems comprising a hot subdwarf paired with a bright main-sequence/giant companion display short-period photometric variations possibly due to irradiation or stellar activity and are also short-period candidates. All except two candidates were drawn from a selection of subluminous stars in the *Galaxy Evolution Explorer* ultraviolet sky survey. Our new identifications also include a low-mass subdwarf B star and likely progenitor of a low mass white dwarf (GALEX J0805–1058) paired with an unseen, possibly substellar, companion. The mass functions of the newly identified binaries imply minimum secondary masses ranging from 0.03 to  $0.39 M_{\odot}$ . Photometric time series suggest that, apart from GALEX J0805–1058 and J2205–3141, the companions are most likely white dwarfs. We update the binary population statistics: Close to 40 per cent of hot subdwarfs have a companion. Also, we found that the secondary mass distribution shows a low-mass peak attributed to late-type dwarfs, and a higher-mass peak and tail distribution attributed to white dwarfs and a few spectroscopic composites. Also, we found that the population kinematics imply an old age and include a few likely halo population members.

**Key words:** binaries: close – binaries: spectroscopic – subdwarfs – white dwarfs – ultraviolet: stars.

## 1 INTRODUCTION

Hot subdwarf stars (see a review by Heber 2009) are core helium burning stars with very thin hydrogen envelopes and belong to the extreme horizontal branch (EHB). The mass of most hot subdwarfs

is about  $0.5 M_{\odot}$ . The origin of EHB stars, i.e., the hot, hydrogen-rich (sdB) and helium-rich subdwarf (sdO) stars, is closely linked to binarity. Mengel, Norris & Gross (1976) first proposed that sdB stars are formed in close binary systems and Dorman, Rood, & O’Connell (1993) inferred the presence of an extremely thin hydrogen envelope ( $< 0.001 M_{\odot}$ ). Han et al. (2002, 2003) proposed three formation channels for sdB stars through binary interaction, i.e., common envelope (CE), Roche lobe overflow (RLOF), and binary merger. Han et al. (2003) predict a binary fraction of 76 - 89 per cent with orbital periods ranging from 0.5 hr to 500 d. However, they caution that the observed frequency could be much lower due to selection effects. The proposed formation channels also predict single sdB stars that form via the merger of two helium white dwarfs. Approximately 11 - 26 per cent of subdwarfs are expected to form via this merger channel (Han et al. 2003).

Formation channels of helium-rich (He-sdO) stars are not as

well defined. Justham et al. (2011) proposed that these objects may form in a close double degenerate binary with the massive component accreting from a helium white dwarf companion and initiating helium-shell burning. A small number of sdO stars are known to exist as companions to Be stars (Gies et al. 1998; Peters et al. 2008, 2013). These sdO stars are formed through close binary interaction where the more massive primary star begins mass transfer onto its less massive companion during its shell-hydrogen burning phase. The result of this mass transfer leaves a spun up Be star with an sdO companion (Pols et al. 1991).

Cool companions to hot subdwarf stars can be revealed as infrared excess in the spectral energy distribution (SED). Thejll et al. (1995) and Ulla & Thejll (1998) detected infrared excess in over 20 per cent of the hot subdwarf stars studied in their sample. Girven et al. (2012) explored photometric surveys that cover a wide wavelength range, from the Galaxy Evolution Explorer (*GALEX*) ultraviolet survey through to the infrared, the Two Micron All Sky Survey (2MASS) and the UKIRT Infrared Deep Sky Survey (UKIDSS), and searched for main-sequence companions to hot subdwarf stars. They found that the most common companions to hot subdwarfs have a spectral type between F0 and K0, while M-type companions were found to be much rarer.

Radial velocity surveys (e.g., Maxted et al. 2001; Morales-Rueda et al. 2003; Copperwheat et al. 2011; Geier et al. 2011a) of sdB stars have shown that approximately half of all sdB stars reside in close binary systems with either a cool main-sequence star or a white dwarf companion. These surveys target binary systems with periods of a few hours to  $\approx 30$  days. Napiwotzki et al. (2004) reported a binary fraction of 39 per cent of sdB stars from the ESO Supernovae type Ia Progenitor surveY (SPY). Copperwheat et al. (2011) estimated a higher binary fraction of 46 - 56 per cent from their survey of sdB stars selected from the Palomar-Green and Edinburgh-Cape surveys.

A few rare sdB stars are found in close orbit with a massive white dwarf ( $M_{\text{WD}} \gtrsim 0.9 M_{\odot}$ ), making them Type Ia supernova progenitors. These systems would first evolve to AM CVn systems before detonating either as a Type Ia or the less energetic Type Ia (Iax) supernova (Bildsten et al. 2007; Fink et al. 2010; Solheim 2010). The first such candidate is KPD 1930+2752 (Maxted et al. 2000a; Geier et al. 2007), with a second candidate, GALEX J1411–3053 (CD–30 11223), discovered as part of our radial velocity survey of *GALEX* selected hot subdwarf stars (Vennes et al. 2012).

Some sdB stars in close binary systems have stellar parameters that fall below the zero-age horizontal branch and probably did not initiate helium burning. Such objects have very low masses ( $\approx 0.2 M_{\odot}$ ) and are the progenitors of extremely low mass (ELM) white dwarfs, which will in time evolve into AM CVn systems. If the companion to these low mass stars is a massive enough white dwarf, then the system may become a Type Ia supernova. The first known low mass sdB star, HD 188112, was discovered by Heber et al. (2003).

Ahmad, Jeffery, & Fullerton (2004) discovered the first double subdwarf binary, PG 1544+488. This helium rich sdB (He-sdB) binary remains, at the present time, unique. The mass ratio determined from the velocity semi-amplitude of the components show that they have a similar mass which suggests that the system emerged from a CE comprised of two nearly identical red giant cores (Şener & Jeffery 2014). Alternatively, Lanz et al. (2004) interpreted the peculiar atmospheric composition of He-sdB stars, such as PG 1544+488, with evolutionary models involving a delayed helium-core flash and convective mixing while descending

on the white dwarf cooling track. Similarly, HE 0301–3039 is a close binary consisting of two sdO stars (Lisker et al. 2004; Stroeer et al. 2007) that may be the outcome of double-core CE evolution (Justham et al. 2011).

Surveys of hot subdwarfs involving photometric time series have uncovered several more low mass sdB stars. Kepler observations revealed that KIC 6614501 is another low mass sdB plus white dwarf system (Silvotti et al. 2012). Also, Maxted et al. (2014) presented 17 eclipsing systems from Wide Angle Search for Planets (WASP) survey that are likely to contain a pre-helium white dwarf, similar to the system 1SWASP J024743.37–251549.2 (Maxted et al. 2011). Follow-up spectroscopy for six of these systems confirmed them to be main-sequence A stars with very low mass ( $\approx 0.2 M_{\odot}$ ) pre-He white dwarfs currently experiencing hydrogen-shell burning.

Wider binaries (orbital periods  $\sim$  years) containing a sdB star with a cool main-sequence companion were reported by Barlow et al. (2012, 2013a) and Vos et al. (2013). The predicted period distribution by Han et al. (2003) is bimodal with some B to F type companions in the longer-period range: The relative frequency of short- to long-period binaries depends on the actual value of the critical mass ratio for stable mass transfer; this ratio may be set with a study of potential subdwarf plus A-star binaries. Chen et al. (2013) showed that these long period binaries are the result of stable RLOF.

Vennes, Kawka & Németh (2011) and Németh, Kawka & Vennes (2012) presented a new sample of sdB stars selected from the *GALEX* all-sky survey and we conducted a radial velocity survey of a subsample of stars from this selection. The first two systems (GALEX J0321+4727 and GALEX J2349+3844) discovered as part of this survey were presented by Kawka et al. (2010), followed by the aforementioned short-period system GALEX J1411–3053 (Vennes et al. 2012; Geier et al. 2013a). Additional spectroscopic and photometric observations of the first two systems were presented in Kawka et al. (2012a) along with a progress report on the other systems that were observed as part of this programme. The photometric observations confirmed the reflection effect in GALEX J0321+4727 originally reported by Kawka et al. (2010) and based on Northern Sky Variability Survey (NSVS) photometry. The observations also showed that both GALEX J0321+4727 and GALEX J2349+3844 are V2093 Her type pulsating subdwarfs (Green et al. 2003).

In this paper, we present spectroscopic and photometric observations of a sample of *GALEX*-selected hot subdwarf stars with the aim of determining their binary properties. Sections 2.1 and 2.2 present details of our spectroscopic observations, while Section 2.3 present archival photometric time series. In Section 3 we present an analysis of stellar properties (3.1), and of binary properties supplemented by our analysis of photometric time series (3.2). Finally, we present a review of the properties of known binaries comprising a hot subdwarf star, including the properties of the components (Section 4.1), the population kinematics (4.2), and the properties of some outstanding individual cases (4.3), followed by a summary of the present work (4.4).

## 2 SAMPLE SELECTION AND OBSERVATIONS

Table 1 lists the stars originally included in our radial velocity survey with notable properties described in Section 3.1. The sample includes 38 spectroscopically confirmed hot subdwarf stars, and two objects that were respectively identified as an early B star

<sup>a</sup> RV: confirmed radial velocity variable star; IR: SED of the stars shows significant IR excess.

and a A V+B V binary. The early B star GALEX J1407+3103 is notable for its high radial velocity, while the close A V+B V pair GALEX J0716+2319 shows significant radial velocity variations on a short time scale. All except two objects were randomly selected from our catalogue of *GALEX*/Guide Star Catalogue ultraviolet-excess objects (Vennes, Kawka & Németh 2011; Németh, Kawka & Vennes 2012). Briefly, the source catalogue includes bright objects ( $N_{UV} < 14$ ) with an ultraviolet excess ( $N_{UV} - V < 0.5$ ). The latter criterion still allows for the selection of hot subdwarf plus F/G dwarf pairs (see Vennes, Kawka & Németh 2011). Two additional stars that were not observed by *GALEX*, including a blue-excess object (Jiménez-Esteban, Caballero, & Solano 2011), are listed at the bottom of Table 1 with J2000 coordinates.

The *GALEX* name corresponds to the coordinates of the ultraviolet source detected in the near ultraviolet (NUV) band (Section 2.3); for convenience, the names are abbreviated to 4 digits right ascension and declination. The ultraviolet coordinates are generally close to the Guide Star Catalog (GSC2.3.2) optical coordinates (<1 arcsec), but, in a few cases, offsets as large as 4 to 9 arcsec occurred (GALEX J1421+7124, J1427–2701, J1902–5130, J2344–3426). Despite the offsets, the ultraviolet and optical sources must be one and the same. These offsets cannot be attributed to a high proper-motion and are most likely due to a distorted point spread function (PSF) in bright off-centred sources in the *GALEX* images (Section 2.3).

Throughout this paper we will refer to the hot subdwarf as the primary and its companion as the secondary. Table 1 lists some no-

table particularities such as the presence of a nearby star, whether unrelated or physically associated to the hot subdwarf, a bright main-sequence companion, or photometric variability due to reflection on a late-type companion or stellar activity (see Section 3.1). Most stars display H $\alpha$ -dominated line spectra, but we also noted the presence of He-rich subdwarfs characterized by He I and He II-dominated line spectra. The stellar parameters of a handful of subdwarfs locate them below the zero-age EHB (ZAEHB) and these objects are likely progenitors of ELM white dwarfs (Sections 3.1 and 3.2).

## 2.1 Intermediate to high-dispersion spectroscopy for radial velocity measurements

Our first extensive set of observations was obtained with the Wide Field Spectrograph (WiFeS, Dopita et al. 2007) attached to the 2.3 m telescope at the Siding Spring Observatory (SSO). The observations were conducted on UT 2011 July 14 to 18, UT 2011 December 2 to 3 and UT 2012 April 27 to 30. We used the B3000 and R7000 gratings with a slit width of 1 arcsec that provided spectral ranges of 3200–5900 Å at a resolution of  $R = \lambda/\Delta\lambda = 3000$  and 5300–7000 Å at  $R = 7000$ , respectively. The RT560 dichroic beam splitter separated the incoming light into its red and blue components. WiFeS is an image-slicing spectrograph with 25 slitlets ( $38 \times 1$  arcsec) and depending on the seeing, the target can cover a few slitlets. The signal-to-noise ratio (S/N) of each observation was maximized by extracting the spectrum from the most significant ( $\lesssim 6$ ) traces. Each trace was wavelength and flux calibrated prior to co-addition. The spectra were wavelength calibrated using NeAr arc spectra that were obtained either prior to or following each observation.

Next, our second set of observations was obtained using the Ritchey-Chrétien Focus (R.-C.) Spectrograph attached to the 4 m telescope at Kitt Peak National Observatory (KPNO) on UT 4 - 6 January 2012. We used the KPC24 grating in second order combined with the T2KA CCD to provide a spectral range of 6030 - 6720 Å and a dispersion of 0.52 Å pixel $^{-1}$ . The slit width was set to 1.5 arcsec which provided a resolution of  $\sim 0.9$  Å or  $R = 7000$ . Contamination from third order was removed using the GG495 filter. The spectra were wavelength calibrated using HeNeAr spectra which were obtained following each observation.

We obtained a third set of observations using the ESO Faint Object Spectrograph and Camera (EFOSC2) attached to the 3.6 m New Technology Telescope (NTT) at La Silla Observatory in September 2012. We used grism number 20 centred on H $\alpha$  providing a spectral range from 6040 to 7140 Å and a dispersion of 0.55 Å pixel $^{-1}$ . We set the slit width to 0.7 arcsec resulting in a 2 Å resolution or  $R = 3500$ . Next, we obtained additional spectra with EFOSC2 on the NTT on UT 31 July and 1 August 2014. We used grism number 19 that provided a spectral range from 4435 to 5120 Å and, after binning  $2 \times 2$ , a dispersion of 0.67 Å per binned pixel. The slit width was set to 1 arcsec resulting in a resolution of  $\sim 2$  Å or  $R \approx 2000$ . Additional EFOSC2 spectra of GALEX J1731+0647 were extracted from the ESO archive (programme 090.D-0012, PI S. Geier). The data were also obtained with grism 19, but binned  $2 \times 1$  resulting in a dispersion of 0.34 Å pixel $^{-1}$ . The slit width was set to 1 arcsec resulting in a resolution of  $\sim 2$  Å. All spectra were wavelength calibrated using HeAr arc spectra which were obtained following each observation.

Also, we obtained a fourth set of spectra using the grating spectrograph attached to the 1.9 m telescope at the South African Astronomical Observatory (SAAO) on UT 2014 February 11. We

used the 1200 lines/mm grating with a blaze wavelength of 6800 Å. This arrangement provided a range of 6023 to 6782 Å with a dispersion of 0.439 Å per pixel. The slit width was set to 1.05 arcsec resulting in  $R = 7000$ , or a resolution of  $\approx 1$  Å at H $\alpha$ . A CuNe comparison arc was obtained following each target observation.

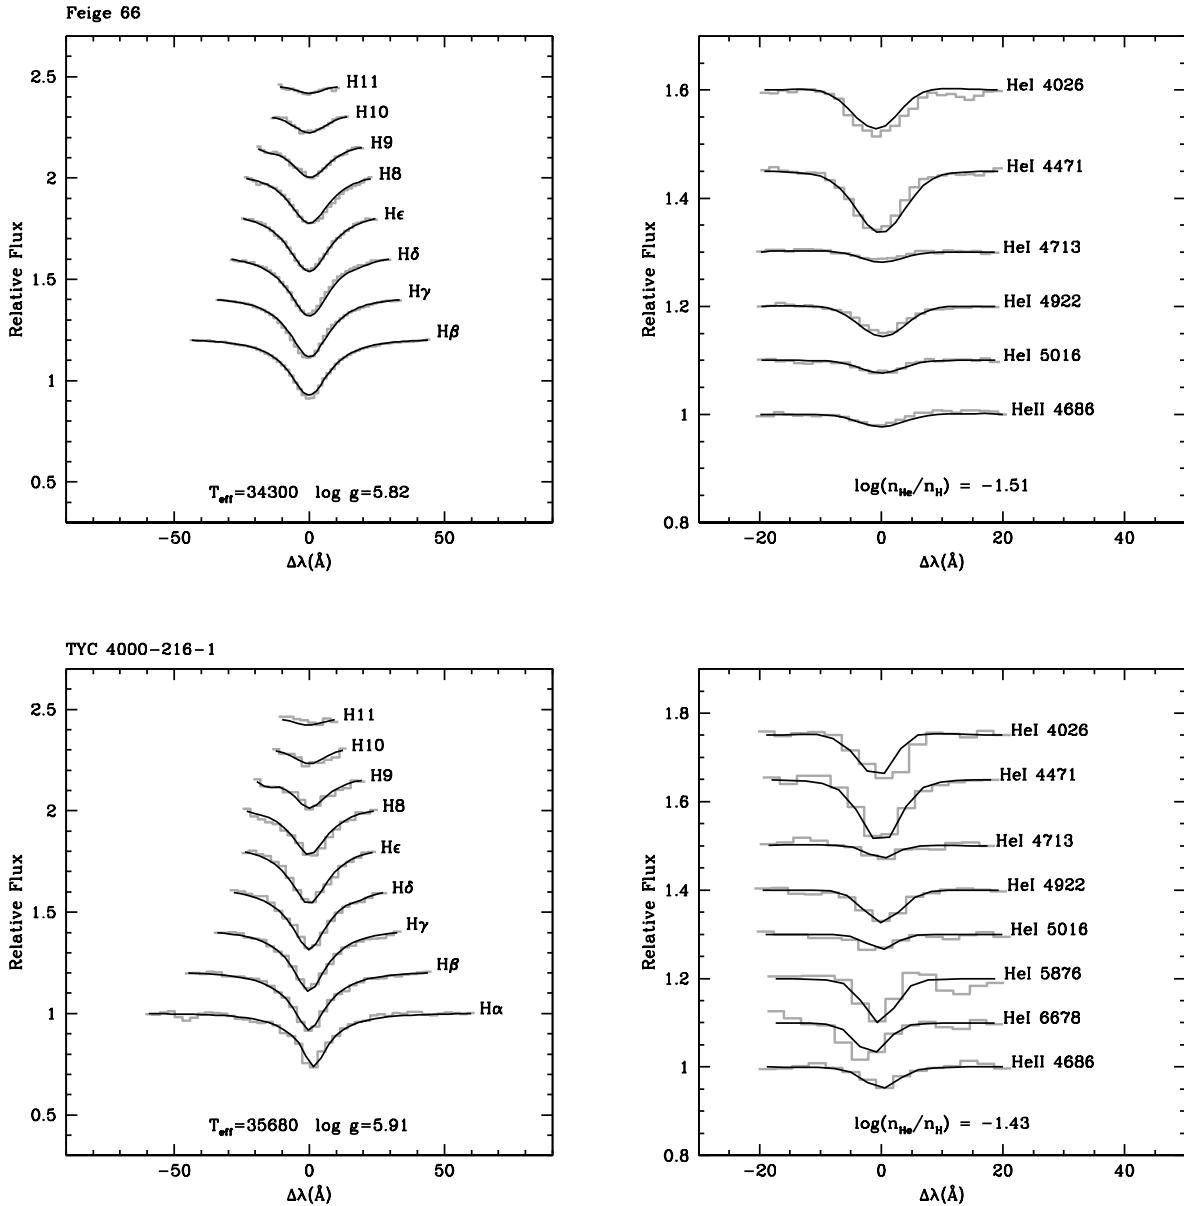

We assembled a fifth data set with observations of the bright objects HD 4539 (GALEX J0047+0958), the spectro-photometric standard Feige 66, GALEX J1421+7124, GALEX J1736+2806, and GALEX J2334+5347 using the 2m telescope at Ondřejov Observatory. The observing configuration and procedure are described in Kawka et al. (2010). Briefly, for each star we obtained a series of spectra centred on H $\alpha$ . We used the 830.77 lines mm $^{-1}$  grating with a SiTe 2030  $\times$  800 CCD, this resulted in a spectral resolution of  $R = 13\,000$ . Each target exposure was immediately followed by a ThAr comparison arc.

Finally, and introducing our sixth and most recent observation programme, we obtained three high-dispersion echelle spectra of the short period binary GALEX J2254–5515. From UT 24 November to 4 December 2014 we used the Fiber-fed Extended Range Optical Spectrograph (FEROS) attached to the 2.2 m telescope at La Silla. The spectra range from  $\approx 3600$  to  $\approx 9200$  Å at a resolution of  $R \approx 48,000$ .

We supplemented our data sets with archival spectra. We extracted processed FEROS data from the ESO archive. The spectra were obtained under the programmes 076.D-0355, 077.D-0515, 078.D-0098 (PI: L. Morales-Rueda) and 086.D-0714 (PI: S. Geier).

We also extracted spectra from the Isaac Newton Group (ING) Archive. The first set of data (GALEX J1632+0759 and GALEX J1731+0647) was obtained with the Intermediate Dispersion Spectrograph (IDS) attached to the Isaac Newton Telescope (INT) on UT 17 May 2013 (run numbers 984456 and 984458) and on UT 19 May 2013 (run numbers 984760, 984762 and 984763). The spectra were obtained with the R1200B grating which resulted in a useful range of 3900 to 5200 Å and a dispersion of 0.48 Å and delivering a resolution of 1.5 Å assuming a 3-pixel full-width at half-maximum (FWHM). The spectra were wavelength calibrated using CuAr and CuNe arcs and adjacent exposures were co-added to obtain the final radial velocity. A second set of data (GALEX J1632+0759) was obtained with the William Herschel Telescope (WHT) and the Intermediate dispersion Spectrograph and Imaging System (ISIS) on UT 26 August 2010 (run numbers 1483813 and 1483814). The spectra were obtained with the R600B and R600R gratings and calibrated with CuAr and CuNe arcs resulting in useful ranges of 3500–5100 Å and 5500–7030 Å and dispersion of 0.88 Å per binned pixel in the blue ( $2 \times 2$ ) and 0.49 Å pixel $^{-1}$  in the red (binned  $2 \times 1$ ), corresponding to spectral resolutions of 1.7 Å in the blue and 1.5 Å in the red assuming a 3-pixel FWHM.

On average, a high signal-to-noise ratio was achieved with EFOSC2 on the NTT ( $S/N \approx 100$ ), the R.-C. Spectrograph on the KPNO 4 m telescope ( $S/N \approx 60$ ), and WiFeS on the SSO 2.3 m telescope ( $S/N \approx 80$ ). A lower signal-to-noise ratio was achieved with the coude spectrograph on the Ondřejov 2 m telescope, FEROS on the MPG 2.2 m telescope (La Silla), and the grating spectrograph on the SAAO 1.9 m telescope ( $S/N \approx 30$ ). The lower S/N achieved at Ondřejov and La Silla is largely compensated by the higher dispersion resulting in comparable or superior velocity accuracy (see next Section). More than 70 per cent of our spectra had a  $S/N \gtrsim 40$  and spectra with ill-defined hydrogen or helium lines ( $S/N \lesssim 15$ ) were rejected.

**Figure 1.** Line profile analysis of the WHT spectrum of Feige 66 (top) and KPNO spectrum of TYC4000-216-1 (bottom), labelled with best-fitting parameters.

### 2.1.1 Tests of the wavelength and velocity scales

We performed a series of tests of the wavelength scale of relevant spectra using the O I sky emission lines and atmospheric molecular absorption bands.

Diffuse O I  $\lambda 6300.304$  emission helps set the accuracy of the wavelength scale, particularly in low- to intermediate-dispersion spectra. A strong emission line is detected in 93 per cent of all usable EFOSC2 spectra, 95 per cent of all KPNO and SSO spectra, and nearly all SAAO spectra. A short exposure time as well as the appearance of scattered moonlight usually limit the usefulness of this template. The O I velocity averaged  $v(\text{O I}) = 0.0 \text{ km s}^{-1}$  at KPNO with a dispersion  $\sigma_v(\text{O I}) = 2.1 \text{ km s}^{-1}$ ,  $v(\text{O I}) = 1.9 \text{ km s}^{-1}$  with EFOSC2 and a dispersion  $\sigma_v(\text{O I}) = 5.4 \text{ km s}^{-1}$ ,  $v(\text{O I}) = 3.7 \text{ km s}^{-1}$  at SSO and a dispersion  $\sigma_v(\text{O I}) = 7.4 \text{ km s}^{-1}$ , and  $v(\text{O I}) = 4.6 \text{ km s}^{-1}$  at SAAO and a dispersion  $\sigma_v(\text{O I}) = 4.4 \text{ km s}^{-1}$ .

The emission line appeared blended in most spectra obtained during bright time at SSO. Based on this analysis the expected accuracy should be of the order of 2–7  $\text{km s}^{-1}$ . The accuracy of the wavelength scale using coudé or echelle spectrographs is normally of the order of 1  $\text{km s}^{-1}$  or better.

Systematic velocity shifts are expected following an improper placement of the star on the slit, particularly if the stellar image is much narrower than the slit width. Excellent seeing conditions are often encountered at La Silla and KPNO. We cross-correlated telluric absorption features in the KPNO and EFOSC2 spectra with a telluric template of identical spectral resolution. We measured an average velocity of  $-0.8 \text{ km s}^{-1}$  with a dispersion of  $13.4 \text{ km s}^{-1}$  in the EFOSC2 spectra and an average velocity of  $2.4 \text{ km s}^{-1}$  with a dispersion of  $10.0 \text{ km s}^{-1}$  in the KPNO spectra. Velocity deviations of up to  $50 \text{ km s}^{-1}$  were found in a few well-exposed EFOSC2 spec-

tra: We corrected the measured stellar velocities at La Silla using the telluric template velocities.

In summary, after applying telluric corrections, we estimate that errors in stellar velocity measurements due to various systematic effects are better than  $\sim 10 \text{ km s}^{-1}$  provided that the photospheric lines are well defined. Ultimately, the accuracy of the wavelength is verifiable using actual stellar data and by plotting the velocity dispersion distribution (Section 3.1.3).

## 2.2 Low-dispersion spectroscopy for stellar parameter determinations

For stars not listed in Németh, Kawka & Vennes (2012), we obtained additional low dispersion spectra with the R.-C. spectrograph attached to the 4m telescope at KPNO on UT 2013 July 12 (GALEX J1421+7124) and 2014 May 24 (GALEX J2334+5347). We used the KPC-10A grating and T2KA CCD with a dispersion of  $2.77 \text{ \AA pixel}^{-1}$  in first order and centred on  $5875 \text{ \AA}$ . We used the order sorting filter WG360 and set the slit width at  $1.5 \text{ arcsec}$  resulting in a spectral resolution of  $\approx 5.5 \text{ \AA}$ . The spectra were wavelength calibrated using the HeNeAr arc.

We extracted a set of spectra of the spectro-photometric standard Feige 66 from the ING archive. These spectra were obtained with ISIS attached to the WHT (run numbers 133198, 133200, 133201, 133223, 133226, 133227). The spectra were obtained using the R300B grating in the blue arm providing a dispersion of  $1.54 \text{ \AA pixel}^{-1}$  and a spectral range from  $3620$  to  $5190 \text{ \AA}$ . The slit width was set to  $2.4 \text{ arcsec}$  for each observation which corresponds to a resolution of  $\approx 7.5 \text{ \AA}$ . The spectra were wavelength calibrated using a CuAr arc.

Details of the low-dispersion spectroscopy obtained of other objects in the present sample are given by Vennes, Kawka & Németh (2011) and Németh, Kawka & Vennes (2012).

## 2.3 Photometry and imaging

We compiled available optical and infrared photometric measurements and combined them with the *GALEX* NUV and FUV photometry from the all-sky imaging survey (AIS) to build a SED for each object in the sample. The ultraviolet data were collected from the site [galex.stsci.edu/GalexView/](http://galex.stsci.edu/GalexView/). Morrissey et al. (2007) present details of the instrument calibration. Table A1 in the Appendix lists the *GALEX* magnitudes, along with the available *V* magnitudes as well as 2MASS (Skrutskie et al. 2006) and Wide-field Infrared Survey Explorer (*WISE*, Wright et al. 2010) infrared measurements.

The PSF of *WISE* images ranges from  $6$  to  $12 \text{ arcsec}$  in the  $3$  to  $24 \mu\text{m}$  wavelength range, while the PSF in 2MASS images is close to  $2.5 \text{ arcsec}$ . Because of its relatively broad PSF, stars located within its range and identified in higher-resolution imaging are certainly contaminating the SED in the mid-IR range.

Also, we extracted photometric time series from the SuperWASP (SWASP, Pollacco et al. 2006) public archive, NSVS (Woźniak et al. 2004), All Sky Automated Survey (ASAS; Pojmanski 1997) and Catalina surveys (Drake et al. 2009). The Catalina photometry is unfiltered. Bright targets ( $< 12 \text{ mag}$ ) are often saturated, but the photometric measurements are more precise with faint targets ( $> 14 \text{ mag}$ ) than those obtained in the other three surveys consulted. The SWASP images are filtered (4000-7000  $\text{\AA}$ ). Light curve analysis of SWASP data is valuable because of the large number of measurements obtained for individual targets. We

obtained ASAS times series in the *V* band and the NSVS images are unfiltered.

The calibrated *GALEX* magnitudes are obtained from the count rates extracted using elliptical apertures (fuv\_flux\_auto, nuv\_flux\_auto) fitted to the actual stellar profiles and converted into the AB system. The average *GALEX* PSF is matched approximately by Gaussian functions with FWHM of  $5.3$  and  $4.2 \text{ arcsec}$  in NUV and FUV images, respectively, and a positional accuracy of  $\approx 0.5 \text{ arcsec}$ . However, several factors affect the reliability of the *GALEX* photometric magnitudes. The *GALEX* imaging quality varies with the detector position with a strong dependency on the radial distance from the image centre. We recorded the target distance to the centre of the field of view (fov\_radius), as well as the actual FWHM values in the FUV and NUV images (fuv\_fwhm\_world, nuv\_fwhm\_world) for each target. Measurements with a radial distance outside of  $0^\circ.4$  combined with a large PSF ( $> 0^\circ.01$ ) or measurements with an exceedingly large PSF ( $> 0^\circ.04$ ) are marked in Table A1 as possibly unreliable. Finally, bright objects with unreliable non-linearity corrections outside the range of validity are marked. Non-linearity effects dominate the photometric error: A 10 per cent loss is observed at  $N_{UV} = 13.9$  and  $F_{UV} = 13.7$  so that most measurements in the present selection are affected. Morrissey et al. (2007) and Camarota & Holberg (2014) propose correction algorithms that are nearly identical. Camarota & Holberg (2014) presented a calibration sample sufficiently large to allow us to evaluate the scatter in the synthetic versus measured magnitude relations. For example, this scatter is of the order of  $0.35$  and  $0.4 \text{ mag}$  at  $N_{UV}$  and  $F_{UV} = 13$ , respectively. We adopted *GALEX* magnitudes adjusted using the correction algorithm of Camarota & Holberg (2014) with errors estimated using the scatter in these corrections for a given magnitude.

The EFOSC2 acquisition images provide a deep, high-spatial resolution view of the fields surrounding target stars. These images were obtained with the Loral/Lesser  $2048 \times 2048$  CCD. With a focal plane scale of  $8.6 \text{ arcsec mm}^{-1}$  and a pixel size of  $15 \mu\text{m}$ , the sky images are sampled with a pixel size of  $0.129 \times 0.129 \text{ arcsec}^2$ , or, after binning  $2 \times 2$ , a pixel size of  $0.258 \times 0.258 \text{ arcsec}^2$ . The images allow for the identification of physical companions or unrelated, nearby stars.

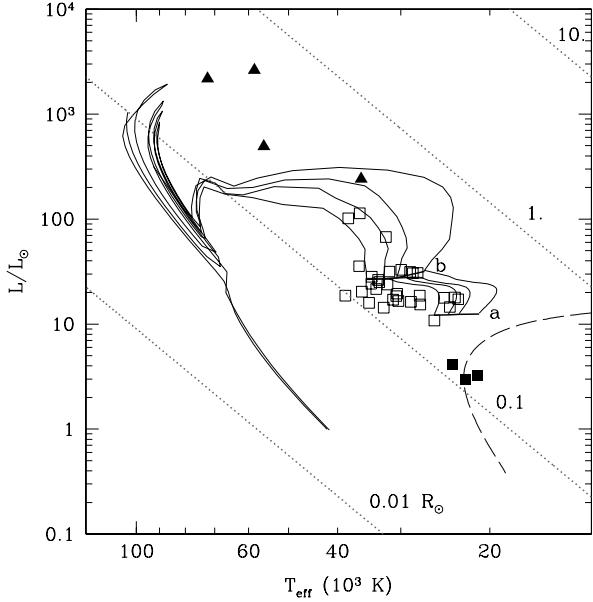

Fig. A1, Fig. A2 and Fig. A3 in the Appendix compare all available photometry to synthetic spectra computed using stellar parameters listed in Table 1.

## 3 ANALYSIS

We present, in order, the properties of the sample including an overview of the stellar parameters ( $T_{\text{eff}}$ ,  $\log g$ ,  $\log \text{He/H}$ ) and evolutionary history, the characteristics of the SEDs and photometric time series, and the radial velocity data set. We identify new binary candidates and present an analysis of individual binary properties from the combined data sets.

### 3.1 Sample properties

Table 1 lists the atmospheric parameters obtained from Németh, Kawka & Vennes (2012). The Balmer line analysis for three additional objects (Feige 66, GALEX J1421+7124 and GALEX J2334+5347) is based on the model grids of Vennes, Kawka & Németh (2011). Best fitting parameters ( $T_{\text{eff}}$ ,  $\log g$ ,  $\log \text{He/H}$ ) are obtained using  $\chi^2$  minimization techniques with the

**Figure 2.** Physical properties, luminosity versus effective temperature, of the sample: sdO stars are shown with full triangles while sdB stars are shown with open squares (assuming  $0.47 M_{\odot}$ ) or full squares (assuming  $0.234 M_{\odot}$ ). The zero-age EHB is labelled “a” while the terminal-age EHB is labelled “b”. Evolutionary tracks computed by Dorman, Rood, & O’Connell (1993) with a helium core mass of  $0.469 M_{\odot}$  and hydrogen envelopes of, left to right,  $0.002, 0.004, 0.006$ , and  $0.01 M_{\odot}$  are shown with full lines. The cooling track from Driebe et al. (1998) for progenitors of ELM white dwarfs of  $0.234 M_{\odot}$  is shown prior to hydrogen shell flashes with a dashed line. Lines of constant radii at  $0.01, 0.1, 1$ , and  $10 R_{\odot}$  are labelled accordingly.

observed line profiles ( $\text{He I,II}$  and  $\text{H I}$ ) being simultaneously adjusted to interpolated spectra from the model grid. Examples of Balmer and helium line analyses are shown in Fig. 1.

Fig. 2 shows properties of the sample presently investigated. Using the effective temperature ( $T_{\text{eff}}$ ) and surface gravity ( $g$ ) we determined the total luminosity (in  $L_{\odot}$ ) by adopting for most objects a sample-average mass of  $0.47 M_{\odot}$  (Fontaine et al. 2012).

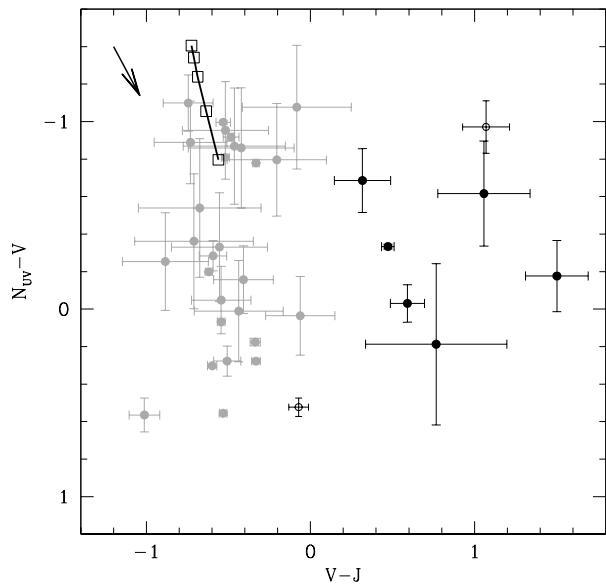

$$L = 4\pi R^2 \sigma T_{\text{eff}}^4,$$

where  $\sigma$  is the Stefan-Boltzmann constant and the radius ( $R$ ) is calculated using

$$R = \sqrt{\frac{GM}{g}},$$

where  $M$  is the subdwarf mass and  $G$  is the gravitational constant.

The sdB stars form a sequence of approximately constant luminosity,  $L = 10\text{--}30 L_{\odot}$  or  $M_V = 4.3$  ( $\sigma = 0.9$ ) mag, and located between the ZAEHB and the TAEHB while a few ageing sdB stars and all He-rich sdO stars set out on a higher luminosity excursion beyond the stable He-burning stage. The objects lying below the ZAEHB ( $L < 10 L_{\odot}$ ) with a low-temperature and a high-gravity, GALEX J0805–1058 and, tentatively, J1411+7037 and J2153–7004, were singled-out and were attributed a mass of  $0.23 M_{\odot}$  based on their likely evolutionary status (Driebe et al. 1998). Most objects lie to the left of the EHB tracks suggesting that their hydrogen layer is thinner than  $0.002 M_{\odot}$ , or, possibly, that their surface gravity is overestimated. To investigate the latter

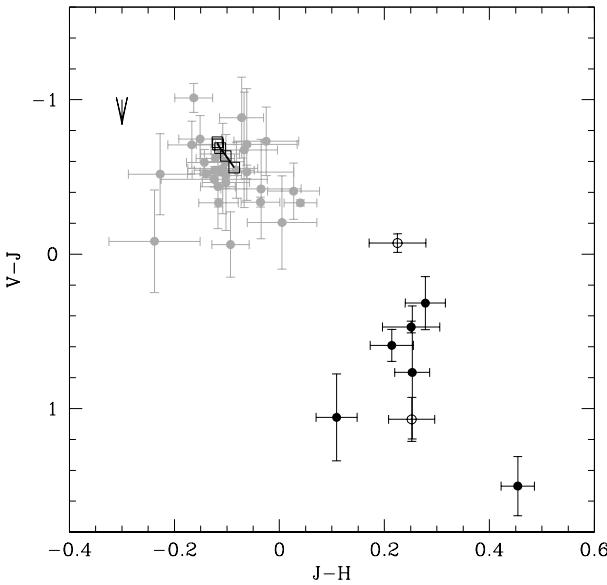

**Figure 3.**  $NUV - V$  versus  $V - J$  colour-colour diagram. Stars with a composite IR excess are shown with full black circles and stars with an IR excess due to a nearby star are shown with open circles (see Section 3.1.1), while all others are shown in grey. Models at  $24, 28, 32, 36$ , and  $40 \times 10^3$  K ( $\log g = 5.7, \log \text{He/H} = -2.5$ ) are shown, from bottom to top, with open squares linked by a full line. The effect of interstellar extinction ( $E_{B-V} = 0.05$ ) on the colours is shown with an arrow in the upper left corner.

possibility, we compared the results of a model atmosphere analysis using the hydrogen Stark broadening tables of Lemke (1997), employed in the present work, to those of Tremblay & Bergeron (2009), which include improved treatment of merging atomic energy levels. We found that improvements in Stark broadening theory may account for a shift of  $\Delta \log g = +0.08$  dex near  $30\,000$  K (see, e.g., Østensen et al. 2014; Telting et al. 2014) in agreement with a shift of  $\Delta \log g = +0.06$  dex found at  $40\,000$  K by Klepp & Rauch (2011). These systematic shifts are notable, but still cannot explain the model offsets apparent in Fig. 2. Metallicity has little effect on temperature and gravity below  $T_{\text{eff}} = 35\,000$  K as demonstrated by Latour et al. (2014). It is worth noting that, while a sdB mass of  $0.47 M_{\odot}$  may be typical, it does not necessarily apply to all objects (e.g., ELM progenitors).

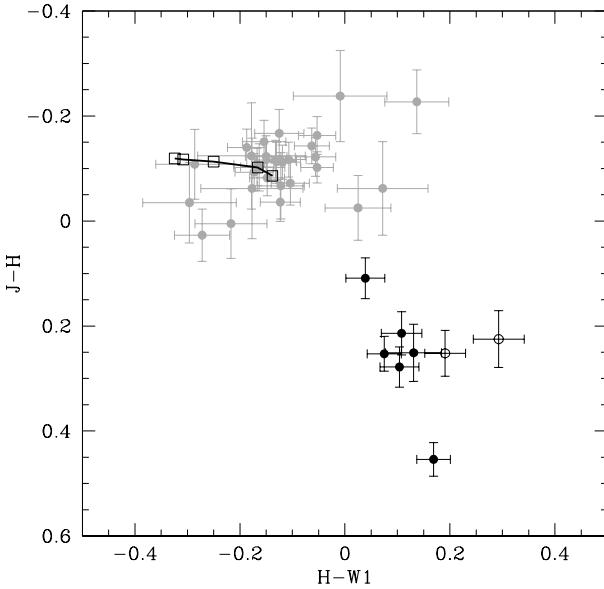

On the other hand, Schindler, Green, & Arnett (2014) pointed out that current evolutionary models fail to reproduce some observed properties of EHB stars, such as the core mass derived from asteroseismology, and concluded that evolutionary models must be updated to match observed seismic and spectroscopic stellar parameters. Schindler, Green, & Arnett (2014) found that very high convective overshooting would be needed to reproduce the seismic core mass but that it would, quite improbably, double the EHB lifetime. Therefore, they conclude that the general treatment of convection in evolutionary models needs updating, and that new opacity tables and diffusion calculations are required.

### 3.1.1 Overview of the SEDs

Fig. 3 shows the  $NUV - V$  versus  $V - J$  colour diagram for the sample of hot subdwarfs listed in Table A1. Fig. 4 and Fig. 5 present the

**Figure 4.** Same as Fig. 3 but showing  $V - J$  versus  $J - H$ .

**Figure 5.** Same as Fig. 3 but showing  $J - H$  versus  $H - W1$ .

$V - J$  versus  $J - H$  and  $J - H$  versus  $H - W1$  diagrams, respectively. The effect of interstellar extinction is evident in the  $NUV - V$  colour of some objects, but many are also affected by large systematic errors in the *GALEX NUV* photometry (non-linearity). For example, a larger extinction than observed in the interstellar line-of-sight is apparent toward GALEX J1632+0759. The International Ultraviolet Explorer (*IUE*) spectra that supplement uncertain *GALEX* photometric measurements indicate  $E_{B-V} = 0.4$ , largely in excess of that found in the extinction map of Schlegel, Finkbeiner, & Davis (1998),  $E_{B-V} = 0.08$ . The effect on ultraviolet colours of an extinction coefficient  $E_{B-V} = 0.05$  (see Fig. 3) is relatively modest, but

coefficients in excess of 0.4 would displace colours from the upper left to the reddened, lower right corner in the vicinity of composite stars.

Individual SEDs may be contaminated by the presence of a nearby star, either physically associated or unrelated to the hot subdwarf. Inspection of the P82, P83, P85 and P89 EFOSC2 acquisition images obtained by Vennes, Kawka & Németh (2011) and Németh, Kawka & Vennes (2012) revealed the presence of nearby companions ( $< 3$  arcsec) to J0047+0337, J0657–7324, and J1632+0759 (see below). Visual inspections of the guiding images displayed at KPNO did not reveal the presence of a nearby companion to any other objects. An inspection of photographic plate material (<http://surveys.roe.ac.uk/ssa/index.html>) helps locate other, more distant objects ( $> 3$  arcsec) that may contaminate photometric measurements with large PSF (e.g., *WISE*). For example, GALEX J0751+0925 is accompanied by a faint ( $\Delta m \sim 5$  mag), nearby star  $\sim 6$  arcsec away at a position angle of  $200^\circ$  (Epoch 1993).

The composite nature of the spectra of GALEX J0047+0337, J1411+7037, J1736+2806, J1753–5007, J2038–2657 (Németh, Kawka & Vennes 2012) are confirmed by their IR photometric colours. The flux contributions in the  $V$  band for these hot subdwarfs are offset by  $\sim 0.7$  (possibly contaminated),  $\sim 0.0$  (weak secondary detection in the optical),  $\sim 1.2$ ,  $\sim 1.3$ , and  $\sim 1.3$  mag, respectively, relative to their observed composite  $V$  magnitudes. Although evident in the IR colours of GALEX J1356–4934 (Fig. A2), the presence of a companion was not detected by Németh, Kawka & Vennes (2012). The flux contribution from the hot subdwarf in the  $V$  band is offset by  $\sim 0.4$  mag relative to the observed composite  $V$  magnitude. We re-examined the spectra of GALEX J1356–4934 and we found weak signatures of a cool main-sequence companion in the blue spectrum used by Németh, Kawka & Vennes (2012), and stronger spectral lines representative of a cool main-sequence star in the red spectra used in this paper. We present our spectral decomposition of this system in Section 3.2.2. The IR colours for GALEX J0047+0337, J0657–7324, and J1632+0759 are almost certainly contaminated by their nearby, resolved companions.

### 3.1.2 Overview of the photometric time series

Table 2 summarizes the photometric time series analyses. We included objects showing significant radial velocity variations (e.g., GALEX J2205–3141), objects with composite optical spectra (e.g., GALEX J1736+2806), and, finally, three objects with previously published analyses from the present survey: GALEX J0321+4727 and GALEX J2349+3844 (Kawka et al. 2010), and GALEX J1411–3053 (Vennes et al. 2012). Photometric variations observed in the sdB plus white dwarf system GALEX J1411–3053 are an example of ellipsoidal variations in this class of objects. Fourier transform calculations of available light curves (Section 2.3) uncovered three objects with significant periodic variations. The light curves were analysed using fast Fourier transform analysis from Press et al. (1992). Both GALEX J1736+2806 and GALEX J2038–2657 are binaries comprising a hot subdwarf with a more luminous optical companion, while GALEX J2205–3141 is composed of a hot subdwarf and late-type companion. The photometric variations in the latter are clearly timed with the orbital period (see Section 3.2) and caused by reflection of the primary on the cool secondary. Variations in GALEX J1736+2806 and GALEX J2038–2657 may be caused by a spot on the surface of the secondary coupled to the rotation period. The variable, double-peaked  $H\alpha$  line profile of

**Table 2.** Photometric time series.

Name	Survey	HJD range (2450000+)	Number	Period range (d)	Semi-amplitude (mmag)	Average magnitude (mag)	Standard deviation (mmag)

<sup>a</sup> Spectroscopic period.<sup>b</sup> Possible spectroscopic period.<sup>c</sup> Ellipsoidal variations at half-spectroscopic period.<sup>d</sup> Photometric period.

GALEX J2038-2657 also implies the presence of surface inhomogeneities (see Section 3.3.1).

An analysis of time series helps constrain the nature of the companion (Maxted et al. 2002). For example, a simple geometric model suggests that the presence of a late-type companion generally leads to detectable photometric variations phased on the orbital period. This reflection effect scales as  $R_2^2$ , where  $R_2$  is the secondary radius, but only as  $a^{-1/2}$ , where  $a$  is the orbital separation (Maxted et al. 2002). Interestingly, an application of these simple relations

confirms the results of detailed light curve modelling and most importantly that, for a given mass function, the effect of a lower binary inclination, which reduces the light contrast between inferior and superior conjunctions as well as its intensity through increased binary separation, is compensated by the increased mass and radius of the secondary calculated using the mass function, hence increasing the fraction of intercepted light. Following Maxted et al. (2002) and adding a slight modification to account for the effect of incli-

nation on the visibility of the exposed hemisphere at inferior and superior conjunctions, the amplitude of the variations is given by:

$$\delta m = 2.5 \log \left( \frac{f^+}{f^-} \right),$$

where

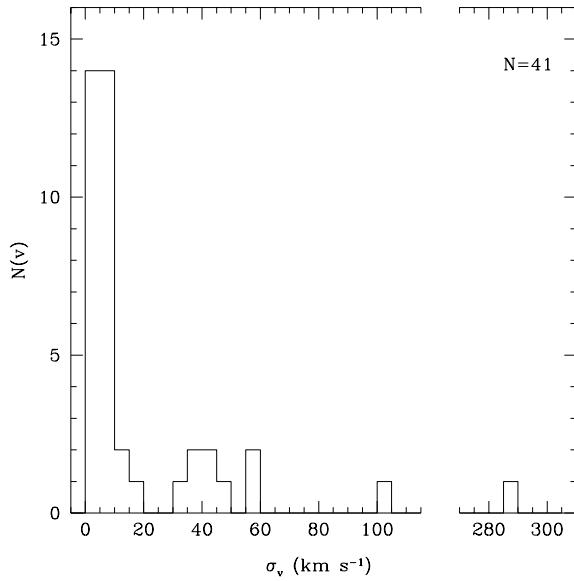

$$f^\pm = 1 + \left( \frac{R_2}{R_1} \right)^2 \left( \frac{R_1}{\sqrt{2}a} \right)^{1/2} \frac{1 \pm \sin i}{2},$$

where  $f^+$  is the relative flux at superior conjunction,  $f^-$  is at inferior conjunction,  $i$  is the binary inclination and  $R_1$  is the primary radius estimated from the measured surface gravity and assumed mass ( $0.23$  or  $0.47 M_\odot$ ). The mass of the putative late-type secondary was estimated using the binary mass function, the assumed primary mass and by varying the inclination angle: The radius is then estimated following the mass-radius relation for late-type stars of Caillault & Patterson (1990). Applications of this approximate formula for  $\delta m$  lead to an overestimation of the amplitude of a factor of  $\approx 3$  when applied to the well known case of GALEX J0321+4727 (Table 2): The semi-amplitude of the phased light curve of GALEX J0321+4727 reaches 44 and 61 mmag in the SWASP and NSVS data sets, respectively, and reveals the presence of an irradiated late-type companion. This simple model also shows that the amplitude of the variations is more or less constant ( $\pm 30$  per cent) when varying the inclination as shown in the detailed models of Maxted et al. (2002). Applying a factor of 0.3 to the amplitude calculated with the simple formula for  $\delta m$  presented above should allow us to confirm or rule out the presence of a late-type companion in the new binaries. For example, the companion to GALEX J2349+3844 (Kawka et al. 2010) is almost certainly a white dwarf: The predicted semi-amplitude of variations due to a late-type companion is  $\approx 70$  mmag, while the observed variations are less than 1 and 5 mmag in the SWASP and NSVS phased light curves, respectively (Table 2). Based on this insight, the photometric times series will help constrain in the following Sections the nature of the companion in the new binaries.

### 3.1.3 Overview of the radial velocity data set

We measured the radial velocities by fitting a Gaussian function to the deep and narrow H $\alpha$  core for most red spectra, or HeI 6678.15 in a few instances described below. In the blue we used the H $\beta$  core, HeII 4685.698, or HeI 4471.48 if necessary (see below). All measured velocities are heliocentric corrected and tabulated in Table B1 in Appendix B. For each target Table B1 also includes the number of spectra, the average velocity ( $\bar{v}$ ) and velocity dispersion ( $\sigma_v$ ).

Fig. 6 shows the distribution of the measured velocity dispersion. The sample includes three objects published earlier (Kawka et al. 2010; Vennes et al. 2012) and seven new identifications described in the following Section. Three additional objects show significant radial velocity variations ( $\sigma_v > 10 \text{ km s}^{-1}$ ), but with insufficient sampling to determine the orbital parameters. Adding two likely close binaries identified through photometric variations (GALEX J1736+2806 and J2038–2657, see Section 3.1.2) but for which we only dispose of radial velocity measurements of the secondary, we estimate that 15 out of 41 hot subdwarfs presently investigated are in close binaries, or a 37 per cent yield, lower than previously estimated (e.g., Copperwheat et al. 2011). Our survey strategy aimed at short-period binaries would be insensitive to long-period, low-amplitude variation ( $< 10 \text{ km s}^{-1}$ ) systems. A detailed comparison with the sample of known hot subdwarf binaries should

**Figure 6.** Number of objects per velocity dispersion bin (width=  $5 \text{ km s}^{-1}$ ). The sample includes data from Table B1 in Appendix B and published results from the same survey (Kawka et al. 2010; Vennes et al. 2012).

allow us to secure a global estimate of binarity in this population (Section 4.1).

## 3.2 Individual properties

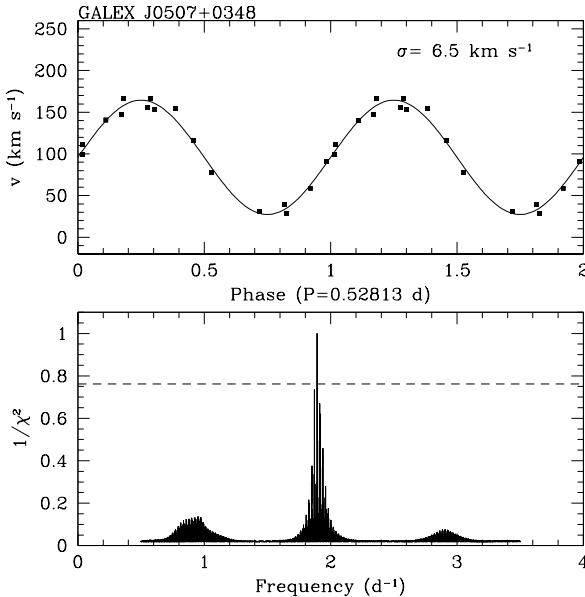

Section 3.2.1 describes objects with variable radial velocities suggesting the presence of a close binary companion: Fig. 7, Fig. 8, Fig. 9, Fig. 10, Fig. 11, Fig. 12, and Fig. 13 show results of the period analysis ( $1/\chi^2$  versus frequency) for this group of objects. The confidence level is set at  $1\sigma$  (66 per cent) for a four-parameter ( $p = 4$ ) analysis with the  $\chi^2$  normalized on the best-fitting solution and the radial velocity measurements phased on the best-fitting period. Sections 3.2.2, 3.2.3, and 3.2.4 review the properties of the remaining systems, i.e., those with composite spectra, unresolved radial velocity variations, or photometric variability, respectively, and the likelihood that they might belong to the close binary population. Finally, Section 3.3 presents known facts concerning the remaining objects. In the following Section, the subscript “1” refers to the hot subdwarf and the subscript “2” refers to its companion. Similarly, the suffix “B” designates the companion. The binary parameters are listed in Table 3 including the number of spectra per object ( $N$ ) and the dispersion in velocity residuals ( $\sigma_{vr}$ ).

### 3.2.1 Close binaries

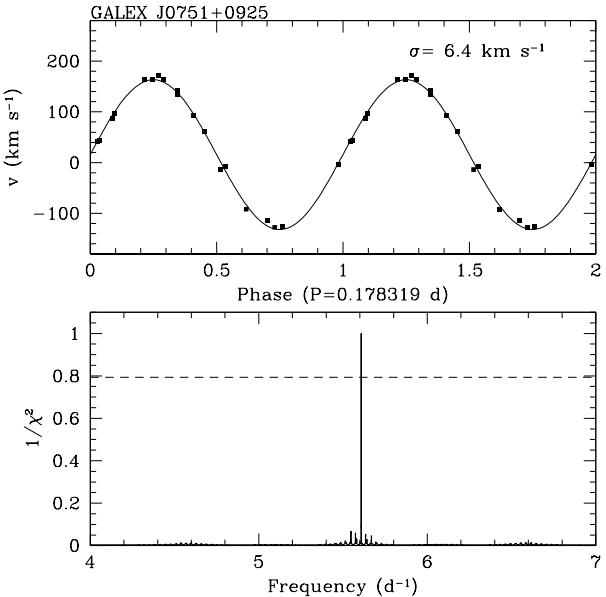

The sdB star GALEX J0507+0348 is part of a newly identified spectroscopic binary. The star is close to the ZAEHB and may be a low-mass sdB star. The H $\alpha$  radial velocity measurements are phased on a period of  $\sim 0.528$  d (Fig. 7). The SED of GALEX J0507+0348 shows an infrared excess but in the *WISE* W3 band only. The nearby object ( $sep. = 17$  arcsec) visible on photographic plates is not likely to affect the *WISE* measurements. Also, low-dispersion spectra show weak CaH&K lines with an equivalent width of  $E.W.(CaK) = 270 \text{ m}\AA$ . The calcium doublet could indicate the presence of a late-type companion. However,

<sup>a</sup> Based in part on the period obtained by Barlow et al. (2014):  $P = 2.951 \pm 0.001$  d.**Figure 7.** (Bottom) period analysis of radial velocity measurements of GALEX J0507+0348 (full line) and 66 per cent confidence level (dashed line). (Top) radial velocity measurements phased on the orbital period (0.52813 d) and best-fitting sine curve (full line) with the dispersion in velocity residuals shown in upper-right. The initial epoch  $T_0$  corresponds to inferior conjunction of the sdB star. Details are presented in Section 3.2.1.

no radial velocity measurements were obtained in that spectral region and we could not confirm variations in the line position. Moreover, we could not confirm the presence of other late-type spectral signatures such as MgI lines, and our composite spectral analysis (Németh, Kawka & Vennes 2012) rejects the presence of a companion with a flux contribution above 1 percent in the optical range. A series of high dispersion spectra is required to determine whether the CaH&K lines originate from the companion, the interstellar medium (ISM), or in the circumstellar environment. The mass function allows us to infer  $M_2 > 0.20 M_\odot$  assuming  $M_1 = 0.47 M_\odot$ , or  $M_2 > 0.15 M_\odot$  assuming  $M_1 = 0.30 M_\odot$ . A late-type (dM,dK) com-

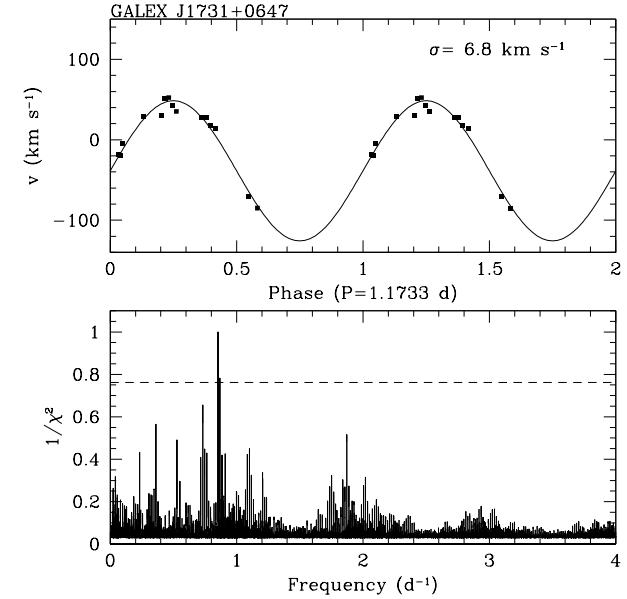

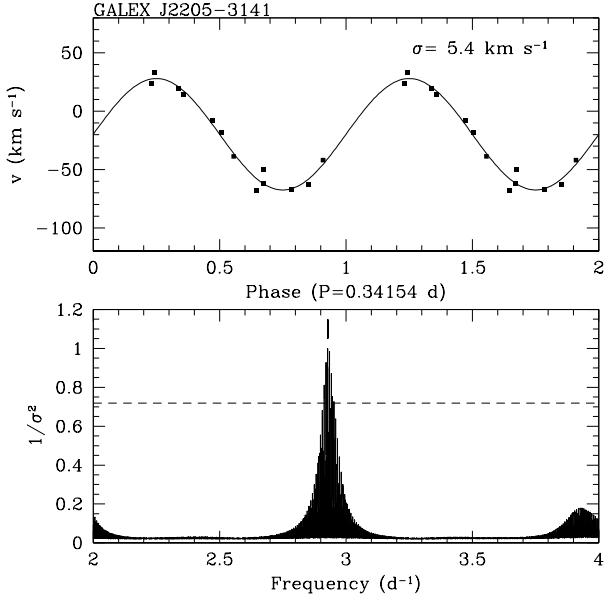

**Figure 8.** Same as Fig. 7 but for GALEX J0751+0925.

panion would satisfy these constraints. However, the Catalina time series folded on the orbital period constrains the photometric variations to a semi-amplitude lower than 2 mmag. Reflection effect on a late-type star with a mass exceeding  $0.2 M_\odot$  would result in variations of a semi-amplitude of  $\approx 60$  mmag as observed in the case of GALEX J0321+4727 (Kawka et al. 2010). We conclude that the companion is most likely a white dwarf: At a binary inclination  $i < 30^\circ$  the mass function implies a minimum mass of  $0.51 M_\odot$  that would be consistent with a normal white dwarf star.

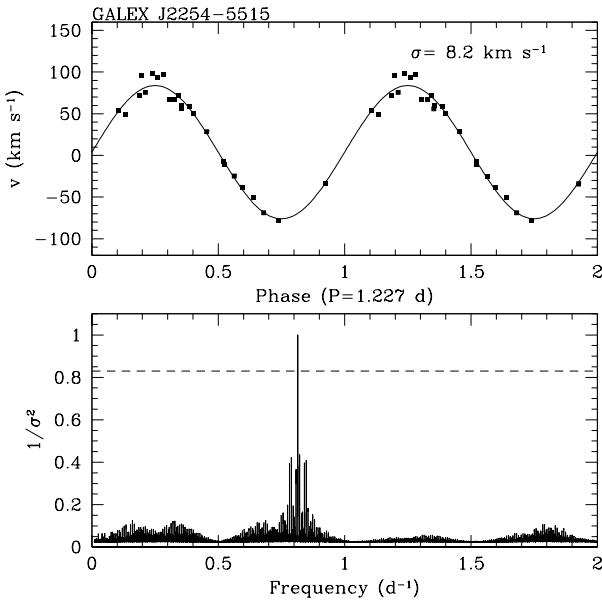

The sdB star GALEX J0751+0925 is part of a close binary with the largest velocity semi-amplitude measured in the present sample,  $K \sim 148 \text{ km s}^{-1}$  (Fig. 8). The mass function implies the presence of a companion relatively more massive than in other similar systems with  $M_2 > 0.34 M_\odot$  assuming  $M_1 = 0.47 M_\odot$ . The SED of this system also appears to show an infrared excess in the W1, W2, and W3 bands which may be caused, in part, by a nearby

**Figure 9.** Same as Fig. 7 but for GALEX J0805–1058.**Figure 10.** Same as Fig. 7 but for GALEX J1632+0759. The tick mark above the best-fitting period indicates the results of the period analysis of Barlow et al. (2014),  $P = 2.951 \pm 0.001$  d.

star only 6 arcsec away (particularly in the W3 band). The Catalina and ASAS light curves do not show significant variations at the orbital period. Again, a comparison with the photometrically variable system GALEX J0321+4727 indicates that the companion is probably a white dwarf. The semi-amplitude of the phased light curve of GALEX J0751+0925 is limited to 4 mmag in the Catalina observations although the minimum secondary mass in this shorter-period system is larger than in GALEX J0321+4727, i.e.,  $0.34$  versus  $0.13 M_{\odot}$ , and the predicted semi-amplitude of variations due to a late-type companion would be  $\approx 190$  mmag. Therefore, the absence of a reflection effect in GALEX J0751+0925 rules out the presence of a late-type companion leaving only the possibility of a  $> 0.34 M_{\odot}$  white dwarf companion, or  $> 0.50 M_{\odot}$  if  $i < 50^{\circ}$ .

**Figure 11.** Same as Fig. 7 but for GALEX J1731+0647.**Figure 12.** Same as Fig. 7 but for GALEX J2205–3141. The photometric period is marked close to the peak frequency of the velocity periodogram.

The sdB GALEX J0805–1058 clearly lies below the ZAEHB (Fig. 2); following the evolutionary tracks of Driebe et al. (1998) the mass of the subdwarf is estimated to be in the range  $0.2$ - $0.3 M_{\odot}$ . The low velocity amplitude (Fig. 9) and small mass function imply a very low mass for the companion,  $M_2 > 0.03 M_{\odot}$ , assuming  $M_1 = 0.234 M_{\odot}$ . At inclinations higher than  $i = 26^{\circ}$ , the secondary mass remains lower than  $0.08 M_{\odot}$  and the object is substellar. Assuming a probability distribution for the inclination an-

**Figure 13.** Same as Fig. 7 but for GALEX J2254–5515.

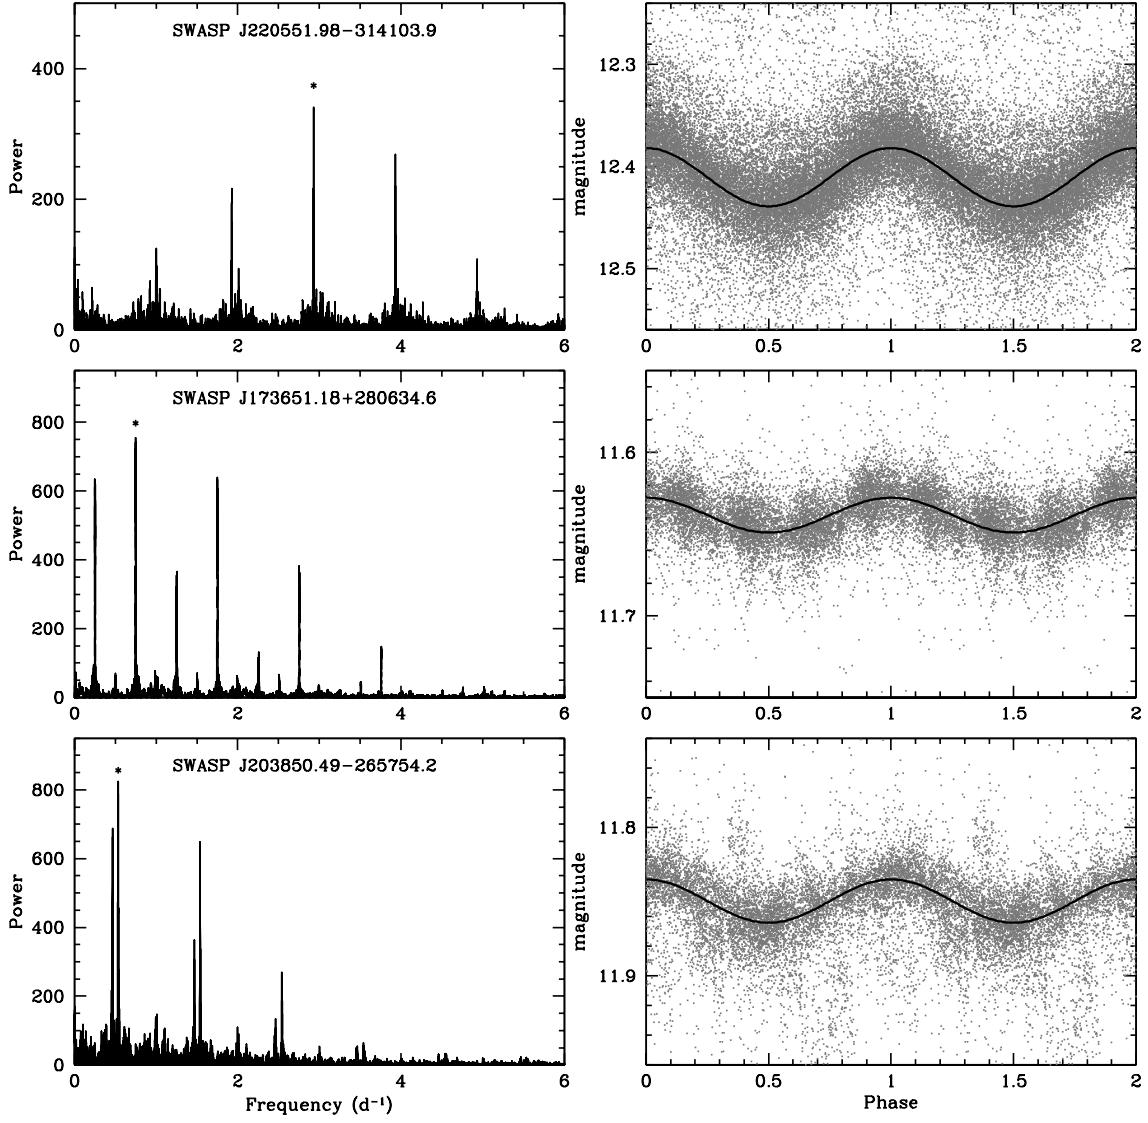

gle  $i$  of the form  $P_i di = \sin i di$ , inclinations higher than  $26^\circ$  have  $P(> 26) = 89.9$  per cent probability of occurring. At lower inclinations ( $10^\circ < i < 26^\circ$ , i.e.,  $P(10 - 26) = 8.6$  per cent), the secondary mass does not exceed  $0.3 M_\odot$  and the object would be a low-mass M dwarf. At very low inclinations ( $i < 7^\circ$ , i.e.,  $P(< 7) = 0.7$  per cent) the secondary would be a normal white dwarf star ( $M > 0.5 M_\odot$ ). The SED shows a single, hot subdwarf star, i.e., as far as the *WISE* W2 band, and the faint ( $\Delta m \sim 6$  mag), nearby ( $sep. \sim 11$  arcsec) object visible in photographic plates does not appear to contaminate the SED. The ASAS and NSVS light curves do not show significant variations when folded on the orbital period, i.e.,  $\lesssim 12$  mmag, while the predicted semi-amplitude of variations due to a substellar object ( $R_2 \approx 0.1 R_\odot$ , see a review by Chabrier et al. 2009) would be  $\approx 20$  mmag. Variations of the order of 10 mmag have been observed in brown dwarf plus hot subdwarf binaries (see, e.g., Schafenroth et al. 2014c) and such variations would be detectable in GALEX J0805–1058 in quality photometric time series. We conclude that the apparent lack of variations is a consequence of the small radius of a substellar secondary.

Barlow et al. (2012) recorded radial velocity variations in spectra of the sdB star GALEX J1632+0759. Their data suggested a period ranging from 2 to 11 days. Our measurements, based on H $\alpha$  and He I 5875.621 in the red, and H $\beta$  and He I 4685.698 in the blue, also revealed large velocity variations (Fig. 10). Recently, Barlow et al. (2014) obtained new radial velocity measurements and determined a period of  $2.951 \pm 0.001$  d. We restricted our period analysis to frequencies between  $0.3$  and  $0.4$  d $^{-1}$  and recovered an identical period. The mass function implies a secondary mass  $M_2 > 0.31 M_\odot$ , assuming  $M_1 = 0.47 M_\odot$ . The SED shows a large flux excess apparent in the 2MASS and *WISE* bands as well as heavy extinction in the ultraviolet range. The measured extinction coefficient ( $E_{B-V} = 0.4$ ) largely exceeds the coefficient inferred from the maps of Schlegel, Finkbeiner, & Davis (1998),  $E_{B-V} = 0.08$ . The additional extinction probably originates in the immediate, possibly dusty, circumstellar environment of the system. An inspection of our acquisition images of GALEX J1632+0759 reveals the presence of a nearby star; we measured a separation of

2.3 arcsec at a position angle of  $225^\circ$ . The 2MASS and *WISE* photometric measurements are likely contaminated by this object. Østensen et al. (2005) also resolved GALEX J1632+0759 and the nearby star and measured a separation of 2.1 arcsec. In addition to GALEX J1632+0759, Barlow et al. (2014) obtained radial velocity measurements of the nearby star which they classified as a late G dwarf or early K dwarf that is itself in a close binary. The radial velocity varied with a period of  $1.42 \pm 0.01$  d. Barlow et al. (2014) also found that the systems share the same systemic velocity suggesting that this is a quadruple system. The ASAS, Catalina, and NSVS time series constrain photometric variations to semi-amplitudes lower than 4, 8, and 18 mmag. The predicted semi-amplitude of photometric variations due to the presence of a late-type companion would be  $\approx 60$  mmag. We conclude that the secondary star is most probably a white dwarf with a mass ranging from  $1.3$  to  $0.5 M_\odot$  assuming a low inclination ( $24 \lesssim i \lesssim 46^\circ$ ), or with a peculiar low mass ( $0.3 - 0.5 M_\odot$ ) assuming  $i \gtrsim 46^\circ$ .

The new binary system GALEX J1731+0647 (Fig. 11) harbours the heaviest binary companion identified in our sample. The mass function implies a mass  $M_2 > 0.39 M_\odot$ , assuming  $M_1 = 0.47 M_\odot$ . The field surrounding this subdwarf is relatively crowded but only two objects are found between 13 and 15 arcsec away and with photographic magnitude differentials  $\Delta m \sim 3$  and 5 mag. These objects would not affect the SED which shows a single hot subdwarf. The lack of photometric variations,  $< 45$  mmag in ASAS time series and  $< 21$  mmag in Catalina time series, compared to expected variations of  $\approx 90$  mmag due to a relatively large M or K dwarf suggests that the companion is most likely a white dwarf. We infer a mass between  $1.3$  and  $0.5 M_\odot$  assuming an inclination of  $29 \lesssim i \lesssim 58^\circ$ , or a peculiar low mass ( $0.4 - 0.5 M_\odot$ ) assuming  $i \gtrsim 58^\circ$ .

GALEX J2205–3141 is a close binary with  $P \approx 0.34$  d (Fig. 12) showing a reflection effect in the SWASP time series (semi-amplitude  $\Delta m \approx 27$  mmag). Similar variations were also observed in the ASAS and Catalina time series. The mass function is consistent with the presence of a late-type companion ( $M_2 > 0.11 M_\odot$ ). Photometric time series from the Catalina survey, SWASP (1SWASP J220551.98–314103.9), and ASAS show variability with mutually consistent periods of  $0.341559 \pm 0.000003$ ,  $0.341563 \pm 0.000002$ , and  $0.341561 \pm 0.000002$  d, respectively. The photometric periods are somewhat longer than the spectroscopic orbital period  $P = 0.341543 \pm 0.000008$  d. The radial velocity measurements are based on the H $\alpha$  4471.48 and 6678.15 lines. We noted that the Balmer H $\alpha$  and H $\beta$  lines cores are asymmetric and are possibly contaminated by emission from the companion as noted in the case of AA Dor (Vučković et al. 2008). Fig. 14 shows the SWASP measurements phased on the photometric period. We identify the initial epoch with the passage of the secondary star at superior conjunction corresponding to maximum reflected light. Although the photometric variations are clearly caused by the reflection of the primary light on a late-type dwarf companion, the phasing error between photometric and spectroscopic ephemeris is  $\Delta\Phi \approx 0.1$ . We attribute this error to a large gap between the epoch of the spectroscopic observations and that of the photometric observations. The SED shows a mild flux excess in the IR to mid-IR range possibly due to the late-type companion. A star found 9 arcsec away and 4 mag fainter does not affect the SED. However, renormalizing on the  $J$  band rather than the  $V$  band nearly eradicates this excess. Assuming a possible  $K$  band contribution from the companion of 15 to 40 per cent, we estimated for the M dwarf companion  $M_{K,2} \approx 7.5$  to  $6.5$  if  $M_{K,1} \approx 5.5$ . Bearing in mind that reprocessing of ultraviolet radiation from the hot primary into

**Figure 14.** (Left panels) Fourier transform analysis of the variable stars GALEX J2205–3141 (top), J1736+2806 (middle) and J2038–2657 (bottom), and phased light curves (right panels). The identification of the photometric period with the spectroscopic period clearly indicates that the light curve of GALEX J2205–3141 shows the effect of reflection of the bright primary on the secondary star. The initial epoch  $T_0$  in GALEX J2205–3141 corresponds to the passage of the secondary star at superior conjunction. Without knowing their orbital periods, we can only state that the cool, secondary stars in both GALEX J1736+2806 and J2038–2657 are variable. The photometric periods are marked with star symbols:  $P = 0.341563$  d (J2205–3141),  $1.333204$  d (J1736+2806), and  $1.870221$  d (J2038–2657).

the cool secondary atmosphere should contribute to this IR excess, the absolute K magnitude of the secondary star corresponds to a spectral type later than M3-4, or a mass  $M_2 \lesssim 0.24\text{--}0.4 M_\odot$  which requires an orbital inclination  $i \gtrsim 20\text{--}30^\circ$ . We find possible evidence of extinction in the ultraviolet range in excess of the extinction expected from the Schlegel, Finkbeiner, & Davis (1998) map, although the GALEX NUV dip may be the result of larger uncer-

tainties than estimated. This system is the only confirmed binary in our sample comprised of a hot subdwarf and late-type companion.

The sdB GALEX J2254–5515 shows large radial velocity variations (Fig. 13) although the Catalina and ASAS time series indicate that the star is not photometrically variable with semi-amplitudes lower than 28 and 5 mmag, respectively. The minimum mass of the secondary,  $M_2 > 0.35 M_\odot$  assuming  $M_1 = 0.47 M_\odot$ , combined with the lack of photometric variability when compared

to expected variations of 150 mmag caused by a reflection effect on a putative late-type companion imply that the companion is a white dwarf.

We neglected the possible effect of orbital eccentricity in the period analysis. The orbits of post-common envelope binaries is expected to be circular due to the synchronization during the post-CE phase. However, eccentric orbits in close binaries containing a subdwarf were reported by Edelmann et al. (2005) and Kawka et al. (2012a). In these cases the eccentricity was small ( $e < 0.1$ ). Larger eccentricities were reported for long period binaries, such as BD+20°3070, BD+34°1543, Feige 87 (Vos et al. 2013) and PG 1449+653 (Barlow et al. 2013a). Eccentric orbits may indicate the presence of a circumbinary disc (Artymowicz et al. 1991).

Now, we summarize additional constraints on the properties of spectroscopic composites, other likely systems showing radial velocity variations, and systems displaying photometric variability.

### 3.2.2 Composite spectra

Using spectral decomposition, Németh, Kawka & Vennes (2012) classified GALEX J0047+0337 as a binary consisting of a hot sdB and a main-sequence F star. The radial velocity measurements obtained for GALEX J0047+0337B imply a constant velocity with standard deviation of only  $6.3 \text{ km s}^{-1}$  and include a single measurement deviating from the average velocity by more than  $10 \text{ km s}^{-1}$ . The ASAS and NSVS photometry do not show evidence of significant variations: The ASAS data constrain potential variations to a semi-amplitude lower than 4.4 mmag for all periods larger than 0.5 hr. The EFOSC acquisition images revealed a nearby star approximately  $\sim 3$  arcsec away at a position angle of  $344^\circ$ . The object is about 1.2 mag fainter in  $R$  and the quoted *WISE* and 2MASS magnitudes include both stars since they would not be resolved in either surveys. Fortunately, our optical spectra were not contaminated by the nearby star and the composite nature of the object is not affected.

GALEX J1411+7037 and J1753–5007 are sdB stars with F-type companions. Their SEDs are consistent with the presence of a luminous companion derived from the spectral decomposition of Németh, Kawka & Vennes (2012). The  $H\alpha$  line profile in each star is dominated by the main-sequence star and no significant radial velocity variations have been found for these objects. The ASAS times series of GALEX J1753–5007 constrain photometric variations to a semi-amplitude lower than 19 mmag.

The SED of GALEX J1356–4934 shows significant infrared excess. An inspection of the acquisition images did not reveal a resolvable, nearby companion and radial velocity measurements show only marginal variability with radial velocity maxima reaching a span of  $20 \text{ km s}^{-1}$ . First, we performed a SED decomposition to estimate the spectral type of the companion. We adopted the sdB parameters determined by Németh, Kawka & Vennes (2012) and calculated sdB absolute magnitudes of  $M_K = 5.47$  and  $M_V = 4.46$ . Adopting the apparent visual magnitude  $V = 12.3$  and 2MASS magnitude  $K = 11.633$  and using the main-sequence colour and absolute magnitude relations from Pecaut & Mamajek (2013), we determined the absolute visual and infrared magnitudes of the late-type companion,  $M_{K,2} = 3.57$  and  $M_{V,2} = 5.36$ , and a distance of 444 pc. Consequently, the companion mass is  $0.94 M_\odot$  corresponding to a G8V star. Next, we performed a spectral decomposition with XTGRID (Németh, Kawka & Vennes 2012) making use of both the blue and red spectra of GALEX J1356–4934. The spectral decomposition showed that the companion contributes 27 per cent of the flux at 7000 Å. The new parameters of the sdB star are

$T_{\text{eff}} = 32370^{+230}_{-660} \text{ K}$ ,  $\log g = 5.72^{+0.07}_{-0.16}$ ,  $\log \text{He/H} = -2.75^{+0.25}_{-0.43}$  and do not differ significantly from our earlier measurements. The parameters of the companion are  $T_{\text{eff}} = 5470$ ,  $\log g = 4.47$ ,  $[\text{Fe}/\text{H}] = 0.003$ , also corresponding to a G8 main-sequence star. These values supersede those of Németh, Kawka & Vennes (2012) for GALEX J1356–4934. The ASAS time series limits the photometric variations to a semi-amplitude of 3 mmag.

Optical spectra of subdwarf plus early-type F-stars are dominated in the red by the companion. Because the mass ratio is  $\gtrsim 3$ , high-dispersion spectroscopy is required to detect the secondary star motion.

### 3.2.3 Radial velocity variable

Other objects, in addition to the confirmed binaries listed in Table 3, are likely close systems. The measured radial velocity extrema suggest that these subdwarfs are in close orbit with a companion, but the small number of spectra did not allow us to perform a period analysis.

We measured velocity extrema  $\Delta v \approx 80 \text{ km s}^{-1}$  for GALEX J0613+3420,  $\Delta v \approx 28 \text{ km s}^{-1}$  for GALEX J0812+1601, and  $\Delta v \approx 35 \text{ km s}^{-1}$  for GALEX J1903–3528. The SWASP time series for GALEX J0613+3420 and GALEX J1903–3528 constrain photometric variations to maximum semi-amplitudes of 13 and 4 mmag, respectively, which exclude the presence of close late-type companions. Further investigations are required to clarify their binary status.

The SED of each object does not reveal the presence of a companion, however the SED of GALEX J0613+3420 shows evidence of a large interstellar extinction (Schlegel, Finkbeiner, & Davis 1998), and a possible excess ( $E_{B-V} = 0.64$ ) above the interstellar value ( $E_{B-V} = 0.36$ ).

### 3.2.4 Photometrically variable

The SWASP light curve of the sdB plus F7V pair GALEX J1736+2806 (1SWASP J173651.18+280634.6) varies with a period  $P = 1.33 \text{ d}$  and a semi-amplitude of 11 mmag (Fig. 14). No significant variations were observed in a nearby comparison object (1SWASP J173635.80+280902.2). The grouping of data points observed in the light curve are also observed in the light curve of the nearby object and, therefore, it must be an artefact of data sampling. Using the SED we found that the absolute  $V$  magnitude of the companion is  $\sim 0.72$  mag brighter than the sdB star consistent with a value of  $\sim 0.81$  mag obtained by Németh, Kawka & Vennes (2012). The absolute magnitude of a late F7 star,  $M_V \sim 4$ , would imply for the hot subdwarf  $M_V \sim 4.7$ ; The atmospheric parameters of the hot subdwarf are very uncertain (Németh, Kawka & Vennes 2012) but would be reconciled with the companion spectral type at the lowest acceptable temperature (30,000K at  $\log g = 5.7$ ). The photometric variability may be caused by irradiation of the exposed hemisphere of the F star although we failed to detect radial velocity variations at the same period.

GALEX J2038–2657 is a relatively luminous hot sdO star with a G type companion (Németh, Kawka & Vennes 2012). Our spectroscopic observations revealed variability in the  $H\alpha$  profile (Fig. 15) on a time-scale of a day or less. However, cross-correlation measurements in the spectral series dominated by the G companion show little variations with a dispersion  $\sigma_v = 7.8 \text{ km s}^{-1}$  comparable to the expected accuracy of the wavelength scale. The

measurements imply that the velocity semi-amplitude of the G8III star does not exceed  $\approx 16 \text{ km s}^{-1}$ . Fig. 16 shows the SED of GALEX J2038–2657 where the ultraviolet range is dominated by the hot subdwarf and the optical range by the red giant. The SWASP time series (1SWASP J203850.49–265754.2) reveals variations of 12 mmag semi-amplitude over a period of 1.87022 d (Fig. 14) that are confirmed by similar variations in a short NSVS time series. Again, no significant variations were observed in a nearby comparison object (1SWASP J203851.22–265943.1). These variations are most likely linked to the observed spectroscopic variability, but they cannot yet be clearly associated to a possible orbital period.

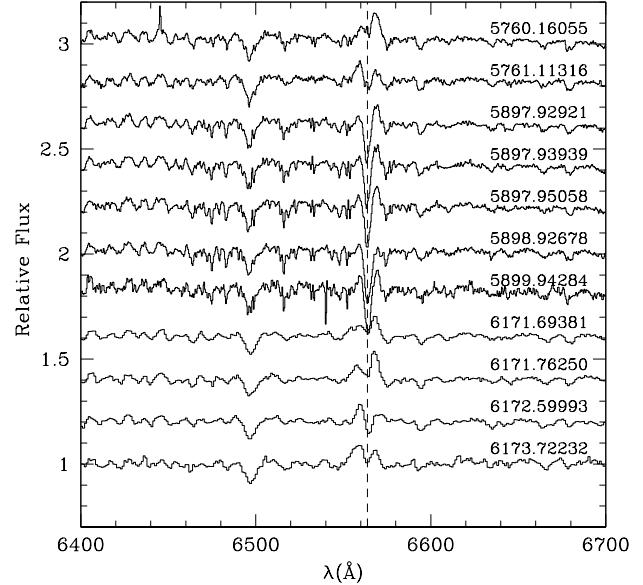

The system shares some properties with the sdB plus K III–IV system HD 185510 (Jeffery et al. 1992; Fekel et al. 1993) and the sdO plus K0 III system FF Aqr (Vaccaro & Wilson 2003). All three systems have an evolved secondary star, from sub-giant to giant, and all three are photometrically variable. However, the hot subdwarf in HD 185510 is possibly the progenitor of a low-mass, helium white dwarf ( $0.3 M_{\odot}$ , Jeffery & Simon 1997). Photometric variations in HD 185510 and FF Aqr coincide with the orbital period and are caused by irradiation of the exposed hemisphere of the secondary stars. Moreover, the orbital periods HD 185510 and FF Aqr are 20.7 and 9.2 d, respectively, with orbital separations of  $\sim 43$  and  $\sim 25 R_{\odot}$ , respectively, and well outside the radius of a sub-giant or giant star ( $R(\text{K0 III}) \approx 16 R_{\odot}$ ).

Without an estimate of the orbital period we can only set limits to the orbital parameters, such as the binary separation. The identification of the late-type giant secondary is based on spectral decomposition (Németh, Kawka & Vennes 2012): The absolute  $V$  magnitude of the hot sdO star is only about  $\sim 1.0$  mag fainter than its companion. Adopting a G8 III type from the spectral decomposition shown in Fig. 16, the absolute magnitude of the companion is  $M_V(\text{G8 III}) = 0.9$ , implying an absolute magnitude  $M_V(\text{sdO}) = 1.9$  for the primary in agreement with the estimate of Németh, Kawka & Vennes (2012),  $M_V(\text{sdO}) = 2.0$ . The minimum orbital period for a systemic mass of  $2.3 M_{\odot}$  and an orbit outside the G8 III radius ( $15 R_{\odot}$ ) is  $P \gtrsim 3.1$  d. Adopting a radius of  $15 R_{\odot}$  for the G8 III star, the photometric period of 1.87 d implies a rotation velocity  $v_{\text{rot}} \approx 350 \text{ km s}^{-1}$ . The narrowest features in the SSO spectra have a width of  $v_{\text{rot}} \sin i = 130 \text{ km s}^{-1}$ , that would enforce a low inclination  $i \lesssim 22^\circ$ . High dispersion spectroscopy is necessary to help determine the orbital parameters and help clarify the origin of the photometric variations. The most likely scenario is that the photometric variations are caused by a surface spot coupled to the rotation of the star, and that the orbital period probably exceeds several days with a low velocity amplitude ( $K \lesssim 20 \text{ km s}^{-1}$ ).

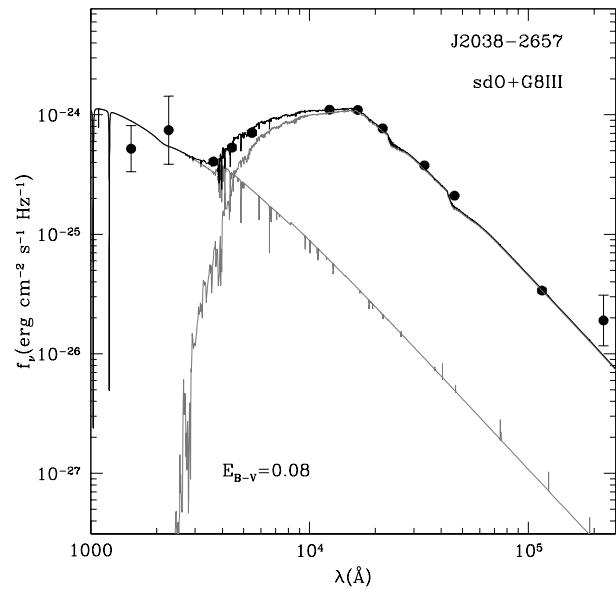

### 3.3 Notes on other objects from this survey

GALEX J0047+0958 (HD 4539) is a well known hot sdB star (see, e.g., Kilkenny 1984). Spectropolarimetric measurements hint at the presence of a weak magnetic field ( $\sim 0.5 \text{ kG}$  Landstreet et al. 2012). Schoenaers & Lynas-Gray (2007) reported line profile variations and radial velocity variations of a few  $\text{km s}^{-1}$  that may be due to g-mode pulsations. Lynas-Gray (2012) obtained photometric series and measured variations with a frequency of  $9.285 \pm 0.003 \text{ d}^{-1}$  and an amplitude of  $0.0023 \pm 0.0003$  mag. This photometric frequency is consistent with one of the frequencies ( $9.2875 \pm 0.0003 \text{ d}^{-1}$ ) determined from low-amplitude radial velocity variations, and both are possibly associated to stellar pulsation.

The SED of GALEX J0049+2056 (Fig. A1) shows an IR excess that could be attributed to a yet unidentified companion or nearby object, or to a dusty environment.

**Figure 15.** Spectra of the photometrically variable sdO+G8III star GALEX J2038–2657 obtained at SSO and La Silla and showing short-term variable H $\alpha$  emission.

**Figure 16.** Spectral energy distribution of GALEX J2038–2657 combining a cool G8III secondary and a sdO primary star (full line). Individual contributions are shown with grey lines. The effect of interstellar extinction ( $E_{B-V} = 0.08$ ) is included.

The sdB GALEX J0059+1544 (PHL 932) is embedded in an emission nebula. However, Frew et al. (2010) have shown that the association is only coincidental, but that PHL 932 does contribute and ionize a dense region of the ISM surrounding it. The SED of this object shows, as in the case of GALEX J0049+2056, a considerable IR excess (Fig. A1). Several radial velocity measurements of PHL 932 were reported in literature. Arp & Scargle

(1967) measured  $15 \pm 20 \text{ km s}^{-1}$  using two low-dispersion spectra. Edelmann (2003) measured  $18 \pm 2 \text{ km s}^{-1}$  using echelle spectra. These velocities are in agreement with our measurements ( $\bar{v} = 16.7, \sigma = 3.1 \text{ km s}^{-1}$ ) and, therefore, it does not appear that PHL 932 is in a close binary. Geier & Heber (2012) report a rotational velocity of  $v_{\text{rot}} = 9.0 \pm 1.3 \text{ km s}^{-1}$ . Landstreet et al. (2012) obtained spectropolarimetric measurements of PHL 932 but did not detect a magnetic field with an upper limit of  $\sim 300 \text{ G}$ .

Brown et al. (2008) classified GALEX J0206+1438 (CHSS 3497) as a hot subdwarf. Our radial velocity measurements vary only marginally ( $\sigma_v < 10 \text{ km s}^{-1}$ ), and we do not dispose of sufficient data to determine a period. A radial velocity measurement of  $V_r = 7 \pm 16 \text{ km s}^{-1}$  was obtained by Brown et al. (2008) and is consistent with our measurements ( $\bar{v} = 13.8, \sigma_v = 7.5 \text{ km s}^{-1}$ ).

GALEX J0232+4411 (FBS 0229+439) was classified as a sdB star in the First Byurakan Survey of blue stellar objects (Mickaelian 2008).

Copperwheat et al. (2011) presented a set of radial velocity measurements for GALEX J0401-3223 which suggest that the sdB star is in a close binary system, but were unable to determine the orbital period with limited data. Copperwheat et al. (2011) measured an average velocity and dispersion of  $v \pm \sigma_v = 55.2 \pm 4.4 \text{ km s}^{-1}$ , consistent with our own measurements. We have combined the Copperwheat et al. (2011) data with ours and conducted a period search. We found a best period of 1.8574 d, however two significant aliases at  $P = 0.64$  and  $0.066 \text{ d}$  cannot be ruled out. The velocity semi-amplitude at all three periods does not exceed  $10 \text{ km s}^{-1}$  and excludes a white dwarf or late-type companion. The relatively short period and low velocity amplitude imply a minimum mass in the substellar range,  $0.01\text{--}0.04 M_{\odot}$ . The SWASP data folded on the best period (1.8574 d) constrain photometric variations to a semi-amplitude of only 1 mmag, or 8 mmag when folded on any periods larger than 0.01 d. The expected variations due to a substellar companion would be as low as 6 mmag at the two longest periods or 20 mmag at the shortest, but are all significantly larger than the SWASP limit. It is not possible to describe the companion with present data, although a substellar companion is a distinct possibility.

Østensen et al. (2010a) obtained series of photometric observations of GALEX J0500+0912 in order to search for pulsations and concluded that it is not photometrically variable. Our limited radial velocity data set does not indicate variability.

An inspection of the acquisition images of GALEX J0657–7324 shows a nearby companion and, therefore, the 2MASS and *WISE* colours of the hot subdwarf are certainly contaminated. Heintz (1992) reported that GALEX J0657–7324 (HEI 714) is a visual double star with a separation of 1.9 arcsec, and our own acquisition image locates the companion 1.8 arcsec away at a position angle of  $270^\circ$ . Also, our optical spectra do not appear to be contaminated by this object and do not indicate variability.

GALEX J1845–4138 is a relatively cool He-rich subdwarf displaying a strong He I line series and weaker Balmer lines. The velocity measurements based on He I 6678.154 ( $v = -59.7 \pm 3.3 \text{ km s}^{-1}$ ) are consistent with the measurements based on H $\alpha$  and do not suggest any variability.

GALEX J1902–5130 is a helium sdO star. Landstreet et al. (2012) obtained spectropolarimetry of GALEX J1902–5130 with a measurement that shows that this star does not have a magnetic field down to a few hundred gauss. Our radial velocity measurements suggest there may be long period, low-amplitude variations. The

measurements are based on He II 6560.088Å. The object is very hot and our spectra display He I emission.

GALEX J1911–1406 is also a very hot He-rich subdwarf. The velocity measurements are based on He II 6560.088Å.

Geier & Heber (2012) report a rotational velocity of  $v_{\text{rot}} = 8.6 \pm 1.8 \text{ km s}^{-1}$  for GALEX J2153-7003. Copperwheat et al. (2011) obtained several radial velocity measurements of this star and found that it is not variable. Their average velocity and dispersion,  $39.4 \pm 7.5 \text{ km s}^{-1}$ , are in a close agreement with our own measurements ( $43.4 \pm 4.2 \text{ km s}^{-1}$ ).

GALEX J2344-3426 is a well known sdB star. Østensen et al. (2010a) obtained photometric series of the star and found it to be non-variable. Geier & Heber (2012) measured a rotational velocity of  $v_{\text{rot}} = 7.3 \pm 1.0 \text{ km s}^{-1}$ . Mathys et al. (2012) and Landstreet et al. (2012) obtained spectropolarimetry of the star and constrained the longitudinal field to 261 G and  $246 \pm 232 \text{ G}$ , respectively.

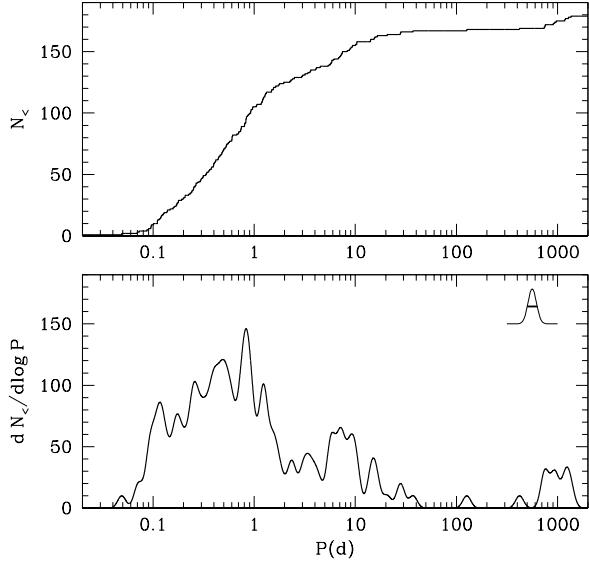

## 4 DISCUSSION

The new binary identifications are placed into context with a compilation of all known spectroscopically identified binaries (Appendix C). Table C1 lists the orbital parameters of these systems. The compilation includes hot subdwarfs with an unseen companion and spectroscopically identified late- to early-type companions in a range of periods from 0.05 to 1363 d. Table C2 lists the properties of the primary as well as kinematical properties of the systems.

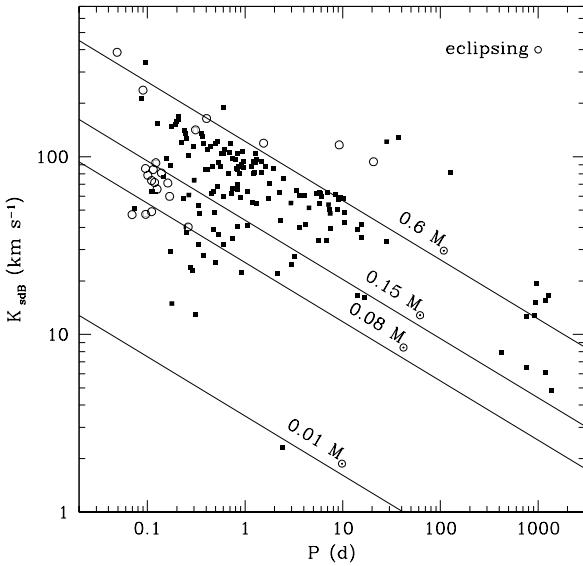

Throughout this discussion we assume for most subdwarfs a mass of  $0.47 M_{\odot}$  with a few exceptions such as the ELM progenitors ( $0.23 M_{\odot}$ ) and hot sdO companions to early-type stars ( $1 M_{\odot}$ ). Using pulsating properties of sdB stars and binary systems for which the sdB mass was measured Fontaine et al. (2012) found that the average mass of a sdB star is  $0.47 M_{\odot}$  with a standard deviation of  $0.031 M_{\odot}$ . Zhang et al. (2009) found that most sdB stars have a mass between  $0.42$  and  $0.54 M_{\odot}$  and an average mass of about  $0.50 M_{\odot}$ . Zhang et al. (2009) used evolutionary models and the parameters of a sample of 164 sdB stars.

### 4.1 Properties of known binaries: Period and mass function

Fig. 17 (top) shows the cumulative distribution of orbital periods in the population of binaries with a hot subdwarf primary. The derivative of the function with respect to the logarithm of the period provides an estimate of the period distribution (Fig. 17, bottom). Several peaks stand-out, particularly at 0.1, 0.5–2.0, 10, and 1000 days. The last two peaks are clearly separated by a gap within which few binaries are known: A few Be stars with a hot subdwarf companion populate the gap and the distribution includes spectroscopically (UV) confirmed Be+sdO (Peters et al. 2008, 2013). We noticed a hint of a hierarchy in the period distribution: The shortest periods coincide with dM companions emerging from a CE phase (low mass ratio  $M_2/M_1 < 1/2$ ), white dwarfs ( $M_2/M_1 \approx 1$ ), and, at high mass ratio ( $M_2/M_1 > 2$ ), subdwarfs with a subgiant/giant or Be companion, and, finally, subdwarfs with a FGK companion at the longest periods and emerging from a RLOF. Following a RLOF, the orbital separation increases the least for more massive companions. It is remarkable that main-sequence A-type star companions are still missing although they are predicted in population syntheses (Han et al. 2003). Subdwarfs with A-type main sequence companions should be detectable as UV excess objects or as low-amplitude radial velocity variations similar to Be+subdwarf binaries. In summary, binaries near the main peak are mostly white dwarfs plus

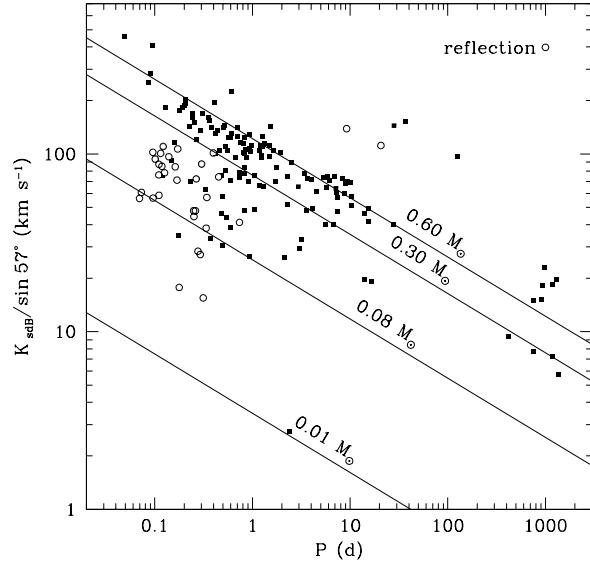

**Figure 17.** Cumulative function of period (top),  $N_<$  versus  $\log P$ , and its first derivative (bottom). The derivative was smoothed with a Gaussian function ( $FWHM = 0.1$  dex), and shown in the upper right corner.

**Figure 18.** Measured velocity amplitude versus period with a sub-sample of eclipsing binaries shown with open circles. Full lines are labelled with the mass of secondary stars which were computed for  $i = 90^\circ$ .

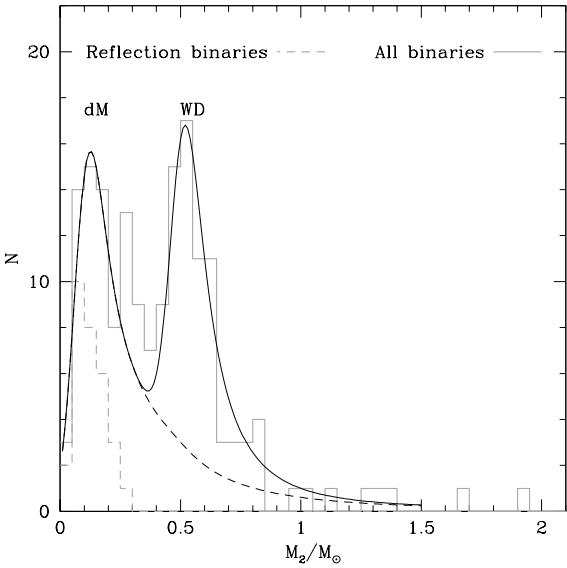

subdwarfs after possibly two episodes of mass-transfer. Note that the orbital parameters of many systems with large velocity amplitudes remain unresolved (see, e.g., Copperwheat et al. 2011; Geier et al. 2011a) and are not included in this analysis.

Fig. 18 shows the sample of known binaries in the velocity amplitude versus period plane. Most eclipsing systems have secondary masses between  $0.08$  to  $0.15 M_\odot$ . Systems with known white dwarf secondaries have secondary masses close to or above  $0.60 M_\odot$ .

**Figure 19.** Same as Fig. 18 but with reflection binaries shown with open circles. The velocity scale is corrected for the effect of an average inclination of  $57^\circ$ . Secondary masses cluster between  $0.08$  and  $0.30 M_\odot$ .

Fig. 19 also shows the sample of known binaries in the velocity amplitude versus period plane but with the velocity scale corrected for an average inclination of  $57^\circ$ . The correction allows to draw class properties but should not be applied to individual objects. Secondary masses for systems showing a reflection effect range, with the exception of FF Aqr and HD 185510, from  $0.08$  to  $0.30 M_\odot$ . Remarkably, secondary masses for most non-reflecting systems cluster near  $0.60 M_\odot$  and the unseen objects are probably white dwarfs. Secondary stars in the long-period range and with masses in excess of  $0.60 M_\odot$  are identifiable as G and K stars. All eclipsing systems with  $K < 100$  km s $^{-1}$ , i.e., with an estimated  $M_2 < 0.3 M_\odot$ , also show a reflection effect indicative of a late-type secondary, while the remaining systems cluster at a higher secondary mass  $M_2 \approx 0.6 M_\odot$  and almost certainly harbour a white dwarf secondary. Fig. 20 shows secondary mass distribution assuming average system inclination of  $57^\circ$ . This distribution may be described by a superposition of two power laws: A shallow distribution with  $M_2 > 0.08 M_\odot$ , i.e.,  $\alpha = 1.3$  between  $0.08$  and  $0.5 M_\odot$  and  $\alpha = 2.3$  above  $0.5 M_\odot$  following the initial mass function  $\xi(m) \propto m^{-\alpha}$  of Kroupa (2001), and a steeper distribution ( $\alpha \approx 6$ ) with  $M_2 > 0.48 M_\odot$ . The former power law encompasses mostly M-type dwarfs, many of them showing a reflection effect, while the latter encompasses white dwarfs in the  $0.5$ - $1.0 M_\odot$  mass range. This simplified white dwarf distribution represents well the peak and high-mass tail of the white dwarf mass distribution (see, e.g., Kepler et al. 2007) but excludes possible low-mass white dwarfs ( $< 0.48 M_\odot$ ). On the other hand, the late-type stellar mass distribution follows the initial mass function and the expectation of a randomly drawn set of late-type stars. The reflection effect is common in short-period binaries ( $P < 0.5$  d) but is relatively rare at longer periods (see Fig. 19) due to increased binary separations and weaker photometric variations: The actual late-type mass distribution appears as a scaled-up version of the secondary mass distribution in the sub-sample of reflection binaries, but it also includes longer period binaries with an indiscernible reflection effect. Note

**Figure 20.** Mass distribution of all known binaries with a hot subdwarf primary star as a function of the secondary mass, assuming an average inclination of  $57^\circ$  (full histogram). The peak distribution of low-mass stars is marked “dM” and that of white dwarfs, “WD”. Binaries showing reflection effect in their light curves are shown with a dashed histogram. The full lines show synthetic distributions smoothed to two-bins width for a combination of late-type stars and white dwarfs (double-peaked full line), and that excluding white dwarfs (dashed line).

that a third narrow peak is possibly present at  $\approx 0.3 M_\odot$ . Since this peak is mostly made up of companions that do not show the reflection effect, the origin of this peak maybe be low-mass white dwarfs. It may also be due to an incorrect mass estimate of the subdwarf, for example an ELM progenitor is assumed rather than a normal subdwarf. Most objects (60-70 per cent) are low mass main sequence stars, while 30-40 per cent are white dwarfs.

Our own survey delivered a 37 per cent fraction of hot subdwarfs in close binaries (Section 3.1.3). Our survey strategy was aimed at and successfully uncovered short-period binaries. Fig. 19 shows that setting our detection threshold at  $10 \text{ km s}^{-1}$  would have allowed for the detection of any stellar companion with an orbital period  $\lesssim 20 \text{ d}$ , any late-type companion with a mass of  $0.3 M_\odot$  and  $P \lesssim 600 \text{ d}$ , or just about any white dwarf companion. However, a close examination of data sampling shows that 60 per cent were obtained with a span of 2 days or less with another 30 per cent with a span of 100-400 days, i.e., during a subsequent observing run or season. Systems with periods of 10-20 days or longer would have only been partially covered and most likely avoided detection. Note that the longest period detected in our survey is only 3 d long. Setting our detection threshold at 10 d, i.e., some 155 objects out of 179 known binaries, the total yield including longer period binaries could be  $\approx 15$  per cent larger for a total binary fraction of 43 per cent. The four additional hot subdwarfs with composite spectra (see Table 1) which are likely to have longer orbital periods ( $\gtrsim 10 \text{ d}$ ) are such objects.

#### 4.2 Properties of known binaries: Kinematics

We calculated the Galactic velocity components ( $U, V, W$ ), which are relative to the local standard of rest (LSR), of all known hot subdwarf binary systems (listed in Appendix C) using their positions, systemic ( $\gamma$ ) velocities, proper motions and apparent magnitudes. We adopted the right-handed system for the velocity components, where  $U$  is positive in the direction of the Galactic centre,  $V$  is positive in the direction of Galactic rotation and  $W$  is positive toward the North Galactic Pole. We assumed that the solar motion relative to the LSR is  $(U, V, W) = (10.1, 4.0, 6.7) \text{ km s}^{-1}$  as determined by Hogg et al. (2005). The distribution of systemic velocities, i.e., radial velocities, follows  $N \approx e^{-|\gamma|/\sigma_r}$ , where  $\sigma_r = 41 \text{ km s}^{-1}$ . The  $\sigma_r$  value is the one-dimension equivalent of the two-dimension transversal velocity dispersion  $\sigma_T = 59 \text{ km s}^{-1}$  measured by Vennes, Kawka & Németh (2011), where  $\sigma_T = \sqrt{2} \sigma_r$ . In their study of the kinematics of EHB stars, Altmann et al. (2004) measured significantly larger radial velocities with a distribution following  $\sigma_r = 65 \text{ km s}^{-1}$  compared to our sample, but they measured a transversal velocity distribution consistent with the present one.

To calculate the Galactic velocity vectors, we employed the method outlined in Johnson & Soderblom (1987) using as an input the radial velocity, proper motion (Zacharias et al. 2013) and distance measurements. We determined the distance toward each subdwarf using the distance modulus  $V - M_V = 5 \log d - 5$ , where the magnitude  $V$  is listed in Table C1. We estimated the absolute magnitude  $M_V$  from the measured stellar parameters, i.e.,

$$M_V = -2.5 \log (4\pi\Omega \bar{H}_V),$$

where  $\Omega = r^2/d^2$ , with  $d = 10 \text{ pc}$  and  $r^2 = GM/g$ . The Eddington flux is averaged ( $\bar{H}_V$ ) over the Johnson  $V$  transmission curve. We assumed  $M = 0.23 M_\odot$  for low-mass objects,  $0.47 M_\odot$  for normal objects and  $1.0 M_\odot$  for subdwarfs in massive binaries, and the published surface gravity measurements were usually obtained using a spectroscopic method similar to that described in Section 3.1.

Fig. 21 shows the  $U$  and  $V$  velocity components for all hot subdwarf binary systems. Table 4 lists the  $(U, V, W)$  velocity components and dispersions for the sample of known binaries. The distribution appears asymmetric with several objects trailing at large negative Galactic  $V$  velocity. We computed the straight average and dispersion (“All”) but excluding the extreme case of OGLE BUL-SC16335. We also fitted the distributions with Gaussian functions excluding outliers, i.e., all bins with less than three members (“ $N > 3$ ”). The sample velocity dispersion is significantly smaller than that calculated by Altmann et al. (2004) for single hot subdwarf stars ( $\sigma_U = 74 \text{ km s}^{-1}$ ,  $\sigma_V = 79 \text{ km s}^{-1}$ ,  $\sigma_W = 64 \text{ km s}^{-1}$ ). However, our velocity dispersion is in better agreement with the dispersion ( $\sigma_U = 62 \pm 8 \text{ km s}^{-1}$ ,  $\sigma_V = 52 \pm 7 \text{ km s}^{-1}$ ,  $\sigma_W = 59 \pm 8 \text{ km s}^{-1}$ ) calculated by de Boer et al. (1997) based on a sample of 41 hot subdwarf stars. Possible explanations for the inflated Galactic velocities of Altmann et al. (2004) are that their sample included yet unidentified binaries or that lower dispersion spectroscopy resulted in larger measurement errors. In summary, the hot subdwarf population and the confirmed binaries among them are kinematically indistinguishable and drawn from the same, general population of EHB stars.

Also, Table 4 compares results for the hot subdwarf population with that of field white dwarf stars. Pauli et al. (2006) list 361 thin disc members and 27 thick disc members, while Kawka et al. (2012b) list 57 old disc white dwarfs, which is a mix of old thin-disc and thick-disk populations, and at least one halo white dwarf.

A comparison of the velocity dispersions shows that the binary population may be an even older population than field white dwarf stars with some population members belonging to the old disc or even the halo.

Four systems display peculiar kinematics. Three of these, SDSS J1622+4730, PHL 861 and SDSS J1505+1108, have Galactic velocities that make them halo candidates with a few additional objects lagging in the  $V$  component making them thick-disk candidates. The fourth object, OGLE BUL-SC16335, is in a crowded field and there is a possibility that the proper motion measurements are incorrect.

Barlow et al. (2013a) calculated kinematics for 5 long period systems and found that two of these (PG 1449+653 and PG 1701+359) have kinematics suggesting that they belong either to the thick disc or halo. They also report that there is a high probability that PG 1104+243 belongs to the thick disc. Our calculated Galactic velocities are similar to those of Barlow et al. (2013a). Note that Barlow et al. (2013a) includes the disc rotation ( $220 \text{ km s}^{-1}$ ) in their  $V$  velocity.

A comparison of the velocity components of the hot subdwarf binary population to that of Kawka et al. (2012b) shows that the dispersion is larger for all velocity components than that of the white dwarf population, suggesting that the subdwarf population appears to be older than the white dwarf population. Finally, a comparison with the work of Pauli et al. (2006) shows that the hot subdwarf binary population has a velocity dispersion between the thin and thick disc dispersions for white dwarfs.

#### 4.3 Low mass subdwarfs as progenitors of extremely low-mass white dwarfs

The first known ELM white dwarf progenitor, HD 188112, was discovered by Heber et al. (2003). As part of their survey of ELM white dwarfs, Kilic et al. (2011) found that SDSS J1625+3632 is similar to HD 188112. Other recently discovered systems are KIC 6614501 (Silvotti et al. 2012) and NGC 6121-V46 (O'Toole et al. 2006). Our radial velocity survey adds one more object to the small sample of ELM white dwarf progenitors: Vennes, Kawka & Németh (2011) showed that GALEX J0805–1058 has atmospheric properties representative of ELM white dwarf progenitors ( $M \lesssim 0.3 M_{\odot}$ ) and, therefore, it was selected for radial velocity follow-up measurements. New radial velocity measurements proved that GALEX J0805–1058 is in a close binary, and, because it also lies below the ZAEHB (see Section 3.1), we conclude that it is a genuine ELM white dwarf progenitor. It is also the first ELM white dwarf progenitor without a more massive white dwarf companion, and this is likely to have significant implications for the origin and evolution of ELM white dwarfs. Two other objects from our sample lie below the ZAEHB, J1411+7037, which is paired with an F star, and J2153–7004, although we did not detect significant radial velocity variations.

#### 4.4 Summary

We presented an analysis of the orbital properties of seven new systems comprising a hot subdwarf primary. The secondary in one system is a late-type star showing a reflection effect (GALEX J2205–3141), while we found evidence that the secondary star in GALEX J0805–1058 is a very low mass M dwarf or possibly a substellar object. The mass function of the other objects implies the likely presence of a white dwarf companion. The

**Figure 21.** Galactic velocity vectors  $U$  and  $V$  of all known binaries containing a hot subdwarf. The individual distributions are shown in the upper panel ( $V$ ) and right panel ( $U$ ). Details of the measurements are shown in Table 4 and discussed in Section 4.2.

period of photometric variability of two additional systems is, in the case of GALEX J1736+2806 probably coincident with the orbital period, and, in the case of J2038–2657, probably coincident with the rotation period of the giant companion. Our survey results, taking into account the survey strategy, imply an incidence of binarity of  $\sim 43$  per cent in the hot subdwarf population.

We have compiled a list of all known hot subdwarfs in binary systems and performed a binary population analysis. We found that systems showing the reflection effect have components that are of a lower mass ( $0.08$  to  $0.30 M_{\odot}$ ) than those that do not show the reflection ( $\sim 0.6 M_{\odot}$ ). It is very likely that the companion to the hot subdwarf in most of the systems not showing the reflection effect in the short period binaries ( $P \lesssim 1$  d) are white dwarfs. The inferred secondary mass distribution is a superposition of two approximate power laws, one low-mass power-law ( $\gtrsim 0.1 M_{\odot}$ ) and composed of low-mass main-sequence stars, and another, high-mass power-law ( $\gtrsim 0.5 M_{\odot}$ ) and primarily composed of white dwarfs with a few

early-type main-sequence stars. White dwarfs constitute  $\approx$ 30–40 per cent of all binary companions.

We have calculated the Galactic velocity components for all known hot subdwarfs in binary system and showed that this population may be older than the field white dwarf population. In this sample, we found three systems that possibly belong to the halo.

Future work will involve high-dispersion spectroscopic follow-up of low-velocity amplitude binary candidates, and of binaries comprising a hot subdwarf and an early-type main-sequence, or giant companion.

## ACKNOWLEDGMENTS

## APPENDIX A: PHOTOMETRY AND SPECTRAL ENERGY DISTRIBUTIONS.

Fig. A1, Fig. A2 and Fig. A3 show available photometry from Table A1 compared to model spectra. The extinction was determined by comparing the observed photometry with the model spectrum. Extinction was measured toward several sdB stars (e.g., Moehler et al. 1990; Aznar Cuadrado & Jeffery 2001) and given that these stars are spread through out the Galaxy, i.e., at high latitudes and in the Galactic plane, the extinction coefficients  $E(B - V)$  can vary from 0 to as much as 0.4. In these cases the extinction was measured using International Ultraviolet Explorer (*IUE*) spectra combined with optical and infrared photometry. We used the parameterized extinction law as defined by Cardelli et al. (1989) with  $R = 3.2$ .

We acquired from the Mikulski Archive for Space Telescopes (MAST) the following set of *IUE* spectra:

J0047+0958: swp26276mxlo and lwp07169mxlo,  
 J0059+1544: swp27142mxlo and lwp07144mxlo,  
 J1435+0013: swp23176mxlo and lwp03501mxlo,  
 J1632+0759: swp33790mxlo and lwp13481mxlo,  
 J1902-5130: swp17051mxlo and lwr13321mxlo,  
 J2344-3426: swp17981mxlo.

The model distributions include the effect of interstellar extinction with the line-of-sight extinction coefficient obtained from Schlegel, Finkbeiner, & Davis (1998). Also, we experimented with larger coefficients in an attempt to match SEDs showing possible intrinsic absorption. For example, the SED of J1632+0759 reveals the presence of an infrared flux excess as well as a larger extinction that revealed in Schlegel, Finkbeiner, & Davis (1998)'s maps.

**Table A1.** Photometric measurements.

## APPENDIX B: RADIAL VELOCITY MEASUREMENTS.

Table B1 lists the heliocentric-corrected velocity measurements ( $v$ ), the mid-exposure heliocentric julian dates (HJD) and data sources. The instrument configurations and error estimates are described in Sections 2.1 and 2.2, respectively, and the measurement procedures are described in Section 3.1.

Stars labelled with the suffix “B” are the “secondary” components of each systems. The radial velocities are those of that secondary component.

The label “SSO” refers to spectra obtained with the Wide Field Spectrograph (WiFeS) attached to the 2.3m telescope at Siding Spring Observatory; the label “KPNO” refers to spectra obtained with the 4-m telescope and R.-C. Spectrograph at Kitt Peak National Observatory; the label “NTT” refers to spectra obtained using EFOSC2 attached to the New Technology Telescope at La Silla; the label “OND” refers to spectra obtained using the coudé spectrograph and the 2-m telescope at Ondřejov Observatory; the label “SAAO” refers to spectra obtained at the South African Astronomical Observatory using the 74-inch telescope and the Cassegrain spectrograph; and new and archival spectra are labelled “FEROS” for the Fiber-fed Extended Range Optical Spectrograph on the MPG 2.2-m telescope at La Silla, and “INT” and “WHT” for spectrographs attached to the Isaac Newton Telescope and William Herschel Telescope at La Palma.

## APPENDIX C: HOT SUBDWARF BINARY SYSTEMS

We have compiled a list of all known hot subdwarf binary systems. Table C1 lists the name of the system, its coordinates, proper motion,  $V$  magnitudes, orbital period in days, the systemic velocity ( $\gamma$ ) and the velocity semiamplitude of the hot subdwarf ( $K$ ). The table also lists the eccentricity ( $e$ ) of the system if the orbit of the binary was found to be eccentric. If the companion to the hot subdwarf is known it is listed and also if the system is photometrically variable, this is also noted in the table. The proper motions and  $V$  magnitudes for the objects are from The fourth U.S. Naval Observatory CCD Astrograph Catalog (UCAC4 Zacharias et al. 2013). For those objects that are not in the UCAC4 and has SDSS photometry, we calculated  $V$  magnitudes using the transformation equation of Jester et al. (2005):

$$V = g - 0.58(g - r) - 0.01$$

The references for the binary system properties are provided in the final column. GALEX J1736+2806 and J2038–2657 are not included in Table C1 because the photometric variations are not clearly associated to orbital periodicities. New Kepler identifications (KIC) are added to the list despite current lack of radial velocity data because of the higher quality of light curve analysis and the timeliness of the results. Table C2 lists published stellar parameters (with relevant references) and calculated absolute  $V$  magnitude and Galactic velocity vectors ( $U, V, W$ ). The mass of sdO companions to Be stars is assumed to be  $1 M_{\odot}$  and that of low-mass sdB stars is assumed to be  $0.23 M_{\odot}$ .
