The paper proposes the modeling and control design of active anti-roll bars. The aim is to design and generate active torque on the chassis in order to improve roll dynamics. The control system also satisfies the constraint of limited control current derived from electrical conditions. The dynamics of the electro-hydraulic anti-roll bar is formulated by fluid dynamical, electrical and mechanical equations. A linear model is derived for control-oriented purposes. The several different requirements and performances for the control motivate the hierarchical handling of the control design. In the hierarchical architecture, the high level improves chassis roll dynamics by a gain-scheduling Linear Quadratic (LQ) control, while the low level guarantees the input limitation and produces the necessary actuator torque by a constrained LQ control. The operation of the designed anti-roll bar control system is illustrated through simulation examples.

1 INTRODUCTION AND MOTIVATION

The improvement of roll dynamics is a relevant problem in vehicles with a high center of gravity. Several roll control systems have been developed which enhance the protection of cargo and improve roll stability. One of the most preferred roll control solutions is anti-roll bars, which increase the stiffness of the suspension system. In this control system, torsion bars connect the left- and right-hand-side suspensions on an axle. Active anti-roll bars are able to adapt to the current road conditions and lateral effects, while roll stability is improved.

Several papers propose methods to reduce the chassis roll motion of road vehicles. Three different active systems are applied, such as anti-roll bars, auxiliary steering angle and differential braking forces [1]. Active anti-roll bars commonly apply hydraulic actuators to achieve appropriate roll moment, see [2]. In [3] an active roll control system based on a modified suspension system is developed with the distributed control architecture. Active steering uses an auxiliary steering angle to reduce the rollover risk of the vehicle. However, this method also influences the lateral motion of the vehicle significantly, see [4]. The advantages of the differential braking technique are the simple construction and low cost, see [5]. In this case

different braking forces are generated on the wheels to reduce the lateral force. Several papers deal with the integration of the above-mentioned systems. In [6] the integration of the active anti-roll bar and active braking is presented. [7] investigates the coordination of active control systems, which could be controlled to alter the vehicle rollover tendencies of the vehicle. The benefits of the integration of anti-roll bars and the lateral control is presented in [8]. Furthermore, the control design of anti-roll bars for the articulated vehicles is a significant and novel topic in [9]. An analysis of the snaking stability of a tractor – light trailer vehicle, where the trailer contains anti-roll bars is presented in [10]. A special construction of semi-active anti-roll bars, which guarantees both ride and roll performances is shown in [11]. The ride and roll performances for active anti-roll system using a PID control are analyzed in [12].

The active system proposed in this paper integrates an electro-hydraulic actuator into an anti-roll bar. The system contains a high-level controller, which improves the roll dynamics of the chassis using active torque, thus the roll motion of the chassis is influenced. The high-level control strategy is realized by a gain-scheduling Linear Quadratic (LQ) controller. The actuator of the anti-roll bar is an oscillating hydromotor with a servo valve on the low level. The actuator control guarantees the generation of the necessary

active torque and satisfies the input constraint of the electric circuit. The control design is based on a constrained LQ method [13]. The goal of the paper is the control design of a multi-level control design of an anti-roll bar system.

The paper is organized as follows. Section 2 presents the control-oriented formulation of chassis roll dynamics and the electro-hydraulic actuator using fluid dynamical, electrical and mechanical equations. Section 3 describes the architecture of the active anti-roll bar control system, and details the design methods of the vehicle dynamics and actuator controllers with demonstration examples. The actuation of the control system is illustrated by a simulation example in Section 4. Finally, Section 5 summarizes the contributions of the paper.

2 CONTROL-ORIENTED SYSTEM MODELING

In this section the mechanical and hydraulic equations expressing the operation of the actuator are presented. The linear vehicle model, describing the roll dynamics of the chassis is modeled, which is enhanced by the active anti-roll bar system. The actuator for this system consists of a hydromotor and a valve. The four degree-of-freedom vehicle dynamical model is illustrated in Figure 1.

2.1 Modeling of chassis roll dynamics

Concerning the rolling motion of the chassis (sprung mass) an anti-roll bar is required in order to reduce the effect of load transfer and roll angle.

The intervention of the anti-roll bar system is a force couple on the unsprung masses, which is provided by an active torque of the electro-hydraulic actuator M_{act} . Lateral force F_{lat} on the vehicle chassis and road excitations on the wheels g_{01} , g_{02} are disturbances working on the system. In the model the masses, spring stiffness, damping ratios and geometrical parameters are constants. h is the distance between the roll center of the chassis and its center of gravity and r is the half-track of the vehicle. The length of the anti-roll bar arm in the longitudinal direction is denoted by a_{arm} . In the model the effects of the side-slip angle and under-/oversteering are ignored.

Fig 1: Illustration of the vehicle model

The vehicle dynamics are derived from the Euler-Lagrange formalism in four second-order differential equations:

$$m\ddot{z} = -(d_1 + d_2)\dot{z} - (d_2r - d_1r)\dot{\phi} + d_1\dot{z}_1 + d_2\dot{z}_2 - (s_1 + s_2)z - (s_2r - s_1r)\phi + s_1z_1 + s_2z_2 \quad (1a)$$

$$I\ddot{\phi} = -(d_2 - d_1)r\dot{z} - (d_1 + d_2)r^2\dot{\phi} - d_1r\dot{z}_1 + d_2r\dot{z}_2 - (s_2 - s_1)rz - (s_1 + s_2)r^2\phi \quad (1b)$$

$$m_1\ddot{z}_1 = d_1\dot{z} - d_1r\dot{\phi} - d_1\dot{z}_1 + s_1z + s_1r\phi - (s_1 + s_{01})z_1 + s_{01}g_{01} + \frac{M_{act}}{2a_{arm}} \quad (1c)$$

$$m_2\ddot{z}_2 = d_2\dot{z} + d_2r\dot{\phi} - d_2\dot{z}_2 + s_2z - s_2r\phi - (s_2 + s_{02})z_2 + s_{02}g_{02} - \frac{M_{act}}{2a_{arm}} \quad (1d)$$

The vertical dynamics of the sprung mass m , and its roll dynamics are described in (1a) and (1b). The vertical dynamics of the unsprung masses m_1 , m_2 are expressed in (1c) and (1d). The proposed dynamical equations (1) are transformed into state-space form as:

$$\dot{x}_{veh} = Ax_{veh} + B_{1,veh}w_{veh} + B_{2,veh}u_{veh} \quad (2)$$

where the state vector of the vehicle $x_{veh} = [z_1, z_2, z, \phi, \dot{z}_1, \dot{z}_2, \dot{z}, \dot{\phi}]^T$ incorporates the vertical displacements of unsprung z_1 , z_2 and sprung masses z , the chassis roll angle ϕ and their derivatives. The control input $u_{veh} = M_{act}$ of the system is the active torque generated by the electro-hydraulic actuator. The disturbances of the system $w_{veh} = [g_{01}, g_{02}, F_{lat}]^T$ are road excitations on the wheels and lateral forces.

2.2 Electro-hydraulic actuator model of anti-roll bar system

The active torque M_{act} is generated by the electro-hydraulic actuator. The actuator that realizes the torque is an oscillating hydromotor, see Figure 2. An oscillating hydromotor is a rotary actuator with two cells, separated by vanes. The pressure difference between the vanes generates a torque on the central shaft, which has a limited rotation angle. The anti-roll bar is split in two halves and the motor connects them. The shaft of the motor is connected to one side of the roll bar and the housing is to the other. When the vehicle chassis rolls, a torque appears in the house which can be countered by the pressure difference in the two chambers provided by a pump.

The hydromotor is connected to a symmetric 4/2 four way valve and the spool displacement of this valve is realized by a permanent magnet flapper motor. Since the presented system has high energy density, it requires small space and it has low mass. Besides, the actuator has a simple construction, but it requires an external high pressure pump [14].

Fig 2: Electro-hydraulic actuator

The physical input of the actuator is the valve current i , the output is the active torque M_{act} . The flapper motor and the spool can be modeled as a second order linear system, which creates a linear dependence between the valve current and the spool displacement. The motion of valve is modeled as:

$$\frac{1}{\omega_v^2} \ddot{x}_v + \frac{2D_v}{\omega_v} \dot{x}_v + x_v = k_v i, \quad (3)$$

where k_v valve gain equals $k_v = \frac{Q_N}{\sqrt{\Delta p_N/2} u_{vmax}}$, where Q_N is the rated flow at rated pressure and

maximum input current, p_N is the pressure drop at rated flow and u_{vmax} is the maximum rated current. D_v is the valve damping coefficient, which can be calculated from the apparent damping ratio. D_v stands for the natural frequency of the valve [15]. Note that the modeling of the valve motion poses several difficulties. Although (3) results a suitable form for control-oriented purposes, the null positioning of the valve is a crucial problem.

The pressures in the chambers depend on the flows of the circuits Q_1 , Q_2 . p_L is the load pressure difference between the two chambers. The average flow of the system, assuming supply pressure p_s is constant:

$$Q_L(x_v, p_L) = C_d A(x_v) \sqrt{\frac{1}{\rho} (p_s - \frac{x_v}{|x_v|} p_L)}. \quad (4)$$

This equation can be linearized around $(x_{v,0}; p_{L,0})$ see [14]

$$Q_L = K_q x_v - K_c p_L, \quad (5)$$

where K_q is the valve flow gain coefficient and K_c is the valve pressure coefficient. In this modeling principle, the hydromotor model does not take into account the friction force and the external leakage flow. The compressibility of the fluid is considered constant [14].

The volumetric flow in the chambers is formed as

$$\dot{p}_L = \frac{4\beta_E}{V_t} (Q_L - V_p \dot{\vartheta} + c_{l1} \dot{\vartheta} - c_{l2} p_L), \quad (6)$$

where β_E is the effective bulk modulus, V_t is the total volume under pressure and V_p is proportional to the areas of vane cross-sections. c_{l1} and c_{l2} are parameters of the leakage flow.

The motion equation of the shaft rotation due to the pressure difference \dot{p}_L and the external load M_{ext} is:

$$J \ddot{\vartheta} = -d_a \dot{\vartheta} + V_p p_L + M_{ext}, \quad (7)$$

where J is the mass of the hydromotor shaft and vanes, d_a is the damping constant of the system. M_{ext} is the effect of disturbances on the chassis roll dynamics. In the linear form the nonlinearities of the friction are ignored.

The active torque of the actuator is determined by p_L . The relationship is written as

(4)

follows:

$$M_{act} = 2p_L A_v a_{arm} \quad (8)$$

where A_v is the area of the vanes and a is the arm of the stabilizer bar in the longitudinal direction.

The control design of the actuator requires the transformation of the previous equations into a state-space form. (3), (6) and (7) are the necessary differential equations, (5) is the part of (6):

$$\dot{x}_{act} = A_{act}x_{act} + B_{1,act}w_{act} + B_{2,act}u_{act} \quad (9a)$$

$$y_{act} = c_{act}x_{act} \quad (9b)$$

The state vector of the actuator model $x_{act} = [x_v \ \dot{x}_v \ p \ \dot{\vartheta}]^T$ contains the spool displacement x_v and its derivative \dot{x}_v , the load pressure p and the shaft angular velocity $\dot{\vartheta}$. The output $y_{act} = M_{act} = u_{veh}$ of the system is formulated using (8). The control input is $u_{act} = i$, while the disturbance is the external load $w_{act} = M_{ext}$.

Finally, the model of the anti-roll bar, incorporating vehicle dynamics (2) and actuator dynamics (9) is formulated as:

$$\dot{x} = Ax + B_1w + B_2u, \quad (10)$$

where $x = [x_{veh} \ x_{act}]^T$, disturbance vector is $w = [w_{veh} \ w_{act}]^T$, the input is $u = u_{act}$ and the matrices are

$$A = \begin{bmatrix} A_{veh} & B_{2,veh}C_{act} \\ 0 & A_{act} \end{bmatrix},$$

$$B_1 = \begin{bmatrix} B_{1,veh} & 0 \\ 0 & B_{1,act} \end{bmatrix}, \quad B_2 = \begin{bmatrix} 0 \\ B_{2,act} \end{bmatrix}.$$

3 HIERARCHICAL DESIGN OF ANTI-ROLL BAR CONTROL

3.1 Performances of the control problem

In the previous section the roll dynamics and the electro-hydraulic actuator have been modeled and a control-oriented model for active anti-roll bar control design has been built. This section proposes the architecture and the optimal design of the control system.

The anti-roll bar control system must fulfill several requirements. The role of the system is to enhance the roll dynamics of the vehicle, which has two main components: the roll angle φ and the roll angular acceleration $\ddot{\varphi}$. First, the roll

angle of the chassis influences the traveling comfort of the vehicle, and the high roll angle increases the risk of the rollover motion. Second, it is also essential to take into account the roll angular acceleration, due to the impulse-like excitations. These road excitations lead to the intense angular acceleration of the chassis, while the roll angle is still small. With the minimization of $\ddot{\varphi}$ the risk of rollover caused by sudden effects can be reduced. The vehicle dynamic performances are formulated such as:

$$z_1 = \varphi \quad |z_1| \rightarrow \min \quad (11a)$$

$$z_2 = \ddot{\varphi} \quad |z_2| \rightarrow \min \quad (11b)$$

The performances z_1, z_2 are arranged in a vector form, such as

$$z = [z_1 \quad z_2]^T \quad (12)$$

Another requirement for the control system is the minimization of the current i , which has two main reasons. First, the applied control energy, which is an economy requirement. Since the valve has a frequent intervention, the minimization of actuation energy is necessary. Second, the current has technical limits, such as $-\dot{i}_{limit} \leq i \leq \dot{i}_{limit}$. Thus, the control input $u = i$ must be minimized:

$$|u| \rightarrow \min, \quad |u| \leq \dot{i}_{limit} \quad (13)$$

Criteria (11) and (13) show that the anti-roll bar system must fulfill several requirements. In the following a cost function J , which incorporates the previous requirements, is formulated. The goal of the control design is to find a controller which minimizes the cost function:

$$J = \frac{1}{2} \int_0^\infty [z^T Q z + u^T R u] dt \rightarrow \min \quad (14)$$

where Q and R are constant weights which influence the solution of the minimization problem. The role of the weights is to find a balance between the performances and the control input.

Although the design criterion (14) provides an adequate description of the control problem, it is hard to find an appropriate solution. The overall formulation of the system (10) contains two subsystems (2) and (9), whose dynamics are different: the dynamics of the chassis is slower than that of the hydraulic actuator. Moreover, the

consideration of the input constraint (13) also poses difficulties at high-order systems. It is beneficial to reduce the states of the system, which is guaranteed by the separation of the two subsystems. Furthermore, it is not necessary to guarantee both of the performances (11) at all the time. Using a changeable balance between the performances a less conservative controller can be achieved. However, it requires the reduction of the system order, which is guaranteed by the separation. In practice the optimization problem (14) is recommended to be divided into two subproblems. It results in two optimal solutions to the subproblems, however, they are suboptimal considering the original problem.

In the following, the overall system (10) is divided into the vehicle (2), and actuator (9) subsystems. These are high level and low level in the hierarchy. The input of the high-level vehicle system is the actuator torque M_{act} , which is the output of the low-level actuator. The interconnection between the subsystems is created by M_{act} .

During the separation the requirements for the controllers must be redefined. The high-level controller must fulfill the vehicle dynamic performances (2). The control input of the high level in anti-roll bar is the active torque M_{act} . Due to economy and technical aspects, M_{act} must be minimized:

$$u_{veh} = M_{act}, \quad |u_{veh}| \rightarrow \min \quad (15)$$

Using the control input M_{act} the roll dynamic performances (2) must be guaranteed. However, physically it is the output of the actuator, see (9). The required control input is computed by the high-level controller and it is denoted by $M_{act,ref}$. The purpose of the low-level control is to guarantee the minimum error between the required and the physical torque. Thus, the next performance is formed for the low-level control design:

$$z_{act} = M_{act,ref} - M_{act} \quad |z_{act}| \rightarrow \min \quad (16)$$

A further requirement for the control input of low-level i is defined in (13).

Based on the separation of vehicle dynamics and actuator, the optimization problem of the cost function J is divided in two parts:

$$\min_K J \leq \min_{K_{high}} J_{veh} + \min_{K_{low}} J_{act}, \quad (17)$$

where

$$J_{veh} = \frac{1}{2} \int_0^\infty [z^T Q_{veh} z + u_{veh}^T R_{veh} u_{veh}] dt \quad (18a)$$

$$J_{act} = \frac{1}{2} \int_0^\infty [z_{act}^T Q_{act} z_{act} + u^T R_{act} u] dt \quad (18b)$$

where K is the optimal controller of the problem (14), K_{high} is the vehicle dynamic controller and K_{low} is the actuator controller. Note that the solutions of the minimizations (17) results in a suboptimal solution to the original minimization problem(14). However, in this way a solution to the constrained optimization problem can be found. The architecture of the hierarchical control is illustrated in Figure 3.

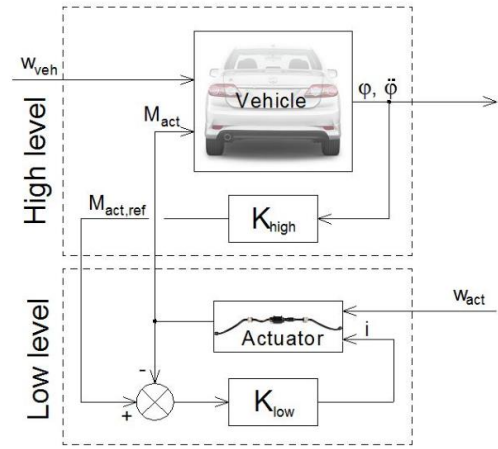

Fig 3: Architecture of control system

3.2 Vehicle level control design

In the following the control design of the high level is presented. The roll dynamic performances of the system are the minimization of the roll angle and the roll angular acceleration, see (11). A further requirement for the control system is the minimization of the control input M_{act} (15). Note that it is not necessary to guarantee all of the requirements at the same time. There are priorities between them, which depend on the current vehicle dynamic status. The priority between the performances is represented with a scheduling variable ρ_{veh} , which is chosen as a linear combination of ϕ and $\ddot{\phi}$:

$$\rho_{veh}(\phi, \ddot{\phi}) = a\phi + b\ddot{\phi} \quad (19)$$

where a and b are design parameters, which represent the balance between φ and $\ddot{\varphi}$. ρ_{veh} is calculated during the measurements of the roll angle and angular acceleration signals. The scheduling variable is taken into consideration in the further design of the control architecture.

Three criteria are defined in Section 3, such as the minimization of φ , $\ddot{\varphi}$ and M_{act} . Using ρ_{veh} , different weights are defined for these criteria, such as:

$$\xi_i(\rho_{veh}) = e^{-\frac{(\rho_{veh}-m_i)^2}{\sigma_i}}, \quad |\xi_i(\rho_{veh})| \leq 1, \quad i = [1; 2; 3] \quad (20)$$

where m_i and σ_i are scale parameters of the curves belonging to the respective criteria. ξ_i weights depend on ρ_{veh} , and the functions have symmetric bell curve shapes, see Figure 4. This is adequately chosen to express the importance of each criterion at a given ρ_{veh} . Where $\xi_i(\rho_{veh})$ has a high value, the consideration of the related criterion has a high priority.

Based on the J_{veh} cost function minimization problem, three different LQ controllers $K_{high,i}$ $i = [1; 2; 3]$ are designed. The resulting $K_{high,i}$ are Linear Quadratic (LQ) controllers computed with different Q_{veh}, R_{veh} weights.

- $K_{high,1}$ operates at low roll angles and low angular accelerations. In the absence of a critical situation the actuator intervention is not necessary. As it saves energy, it is an economical mode of the anti-roll bar system. The weights of the LQ control design are $Q_{veh} = R_{veh}$.

- $K_{high,2}$ controller is activated when φ and $\ddot{\varphi}$ increase. It is essential to take into account both conditions, e.g. at impulse-like excitations angular acceleration of the chassis increases, while the roll angle is still small. With this approach the risk of a rollover caused by sudden effects can be reduced. The weights of the LQ control design are $Q_{veh} > R_{veh}$, which guarantees the appropriate actuation.

- $K_{high,3}$ has an important role in the limitation of M_{act} , see (16). This controller prevents the actuator from being overload. The weights of the LQ control design are $Q_{veh} < R_{veh}$, which guarantees a reduced actuation. If there exists a Common Lyapunov Function P_{high} of the controllers $K_{high,i}$, then the global stability of the closed-loop systems is guaranteed [16].

(a) $\xi_i(\rho_{veh})$ functions

(b) Example on a K_{high} element

Fig 4: Scheduling variable dependence in high level control

The control strategy of the high level control is based on the designed $K_{high,i}$ controllers and the scheduling variable-dependent $\xi_i(\rho_{veh})$ weights. In this way a gain scheduling LQ controller is formed:

$$K_{high} = \frac{\xi_1(\rho_{veh})K_1 + \xi_2(\rho_{veh})K_2 + \xi_3(\rho_{veh})K_3}{\xi_1(\rho_{veh}) + \xi_2(\rho_{veh}) + \xi_3(\rho_{veh})} \quad (21)$$

where K_{high} is the convex combination of $K_{high,i}$. The convexity is guaranteed by the existence of P_{high} and the condition $|\xi_i(\rho_{veh})| \leq 1$. Thus, K_{high} is inside of the convex hull of $K_{high,i}$. Figure 4 illustrates an example, where an element of K_{high} based on (21) is computed.

3.3 Actuator level control design

The torque tracking low-level actuator design is proposed below. The controller K_{act} is designed based on the minimization of J_{act} , using the constrained Linear Quadratic control method. The purpose of the controller is to guarantee the required active torque of the high-level dynamic

controller and satisfy the input constraint of the low level, see (16) and (13).

The low-level LQ controller is based on a piecewise linear control strategy. This method can be used for the approximation of nonlinear systems using linear sections. Piecewise linear systems are special types of switched linear systems with state-space partition-based switching. The main difficulty in this strategy is the switching between the controllers, which can cause transients in the control system [17].

The tracking criterion (16) of the control system requires the reformulation of the state-space equation described in (9). The plant (9) is augmented with an integrator on signal M_{act} to achieve zero steady-state error. The augmented system is as follows:

$$\begin{aligned} \begin{bmatrix} \dot{x}_{act} \\ \dot{z}_{act} \end{bmatrix} &= \begin{bmatrix} A_{act} & 0 \\ -c_{act} & 0 \end{bmatrix} \begin{bmatrix} x_{act} \\ z_{act} \end{bmatrix} + \begin{bmatrix} B_{1,act} \\ 0 \end{bmatrix} w_{act} + \\ &\begin{bmatrix} B_{2,act} \\ 0 \end{bmatrix} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} M_{act,ref} = \tilde{A}_{act} \tilde{x}_{act} + \\ &+ \tilde{B}_{1,act} w_{act} + \tilde{B}_{2,act} u + \begin{bmatrix} 0 \\ 1 \end{bmatrix} M_{act,ref} \end{aligned} \quad (22)$$

The LQ controller design is based on the minimization of the following cost function (17), which incorporates the previous conditions (16), (13) and the augmented plant (22). The weights Q_{act} and R_{act} have an important role in satisfying input constraints. The minimization $\min_{K_{low}} J_{act}$ problem leads to a continuous-time control algebraic Riccati equation:

$$\begin{aligned} P_{low} \tilde{A}_{act} + \tilde{A}_{act}^T P_{low} - \\ - P_{low} \tilde{B}_{2,act} R_{act}^{-1} \tilde{B}_{2,act}^T P_{low} + Q_{act} = 0 \end{aligned} \quad (23)$$

where P_{low} is the solution to Riccati equation, \tilde{A}_{act} and $\tilde{B}_{2,act}$ are the block matrices of (22). The optimal state feedback LQ controller K_{low} is derived from P_{low} .

Since the electric circuit of the actuator has physical limits, it is necessary to prevent the valve current from exceeding the limit u_{const} . In the conventional formulation of the LQ problem (17) it can be ensured by a high R_{act} weight. It results in a conservative controller K_{low} with small gain, which leads to a reduced control input and the degradation of z_{act} tracking performance simultaneously. Moreover, a large LQ gain enhances the tracking performance, but it is likely to violate the input constraint u_{const} . A way to

guarantee (16) and input constraint satisfaction is presented in [13]. In this paper an iterative LQ control design method is proposed which yields a switching LQ controller. In the method numerous controllers are designed using different R_{act} weights. The iterative function for control design is as follows:

$$R_{act,i} = \frac{\sqrt{\rho_{act,i}}}{u_{const}} \sqrt{(\tilde{B}_{2,act}^T P_{low,i-1} \tilde{B}_{2,act})} \quad (24)$$

In the method the different $R_{act,i}$ weights are used at fixed Q matrices, $\rho_{act,i}$ is the actual gain scaling parameter and u_{const} is the input constraint. $P_{low,i-1}$ is the solution of the $(i-1)^{th}$ Riccati equation (23).

The solution to i^{th} Riccati equation is $P_{low,i}$, from which the i^{th} optimal LQ control can be computed. Besides, $P_{low,i}$ determines an ellipsoidal invariant set ε_i in the state-space, where the input constraint can be satisfied. As a result of the iterative design, numerous LQ gains and invariant sets are computed. The controller with the largest LQ gain belongs to the smallest ellipsoid. Based on the invariant sets, a switching strategy is defined to guarantee the input constraint. In the strategy the trajectory of \tilde{x}_{act} is monitored. When the trajectory reaches the set border of an ellipsoid and moves outwards, the system switches to a more conservative controller with a smaller LQ gain. The switching function is formulated as follows:

$$\text{sign}(\rho_{act,i} - \tilde{x}_{act}^T P_{low,i} \tilde{x}_{act}) < 1 \quad (25)$$

If (25) is not satisfied, then \tilde{x}_{act} is out of the i^{th} ellipsoid, thus it is necessary to switch to the $(i-1)^{th}$ controller.

The solution of the switching algorithm is always the smallest ellipsoid, which contains \tilde{x}_{act} . In the method it is necessary to guarantee that \tilde{x}_{act} never departs the largest ellipsoid ε_1 . Therefore $\rho_{act,1}$ must be chosen sufficiently high not to violate this condition. Since the system states are always in the outermost invariant set, the stability of the system is guaranteed. The switching algorithm described above is illustrated in Figure 5.

Fig 5: Invariant sets and switching of a two-state system

4 SIMULATION EXAMPLE

In this section the operation of the active anti-roll bar control is presented during a simulation example. The data of the full vehicle are presented in Table 1.

m	1300kg	d_1	4500 Ns/m	d_2	4500 Ns/m
I	500kgm ²	s_1	50.000 N/m	s_2	50.000 N/m
r	0.8m	h	0.7m	s_0	200.000 N/m
a_{arr}	0.3m	ω_v	7301/s	s_0	200.000 N/m

m_1	120kg	m_2	120kg		

Table 1: Data of vehicle and actuator models

The vehicle contains one anti-roll bar on the rear axle, which actuates to improve the roll dynamics of the vehicle.

The high-level gain-scheduling LQ control computes the currently required torque $M_{act,ref}$. The parameters in the scheduling function $\rho_{veh}(\varphi, \ddot{\varphi})$ are chosen as $a = 1.92$ and $b = 0.528$. In the low-level constrained LQ control $n = 7$ controllers are designed. In the example $n = 1$ LQ control has the highest gain, which improves the tracking performance; while $n = 7$ is the most conservative, which satisfies the constraint $i_{limit} = 0.3A$. Scheduling variable

ρ_{veh} and the number of the low-level controls are chosen based on the previously defined control strategy during the simulations.

(a) F_{lat} disturbance on chassis

(b) Road excitations

Fig 6: Disturbances on the vehicle

The simulation example is illustrated in Figures 6-7. The driver performs an abrupt cornering maneuver with 0.2g maximum lateral acceleration, see Figure 6. It results in the increase of φ and $\ddot{\varphi}$, as shown in Figures 7(a) and 7(b). In the figures two scenarios are compared: a vehicle with an anti-roll bar and an uncontrolled case. The improvement of roll dynamics can be seen during the reduction of φ and $\ddot{\varphi}$ signals. The anti-roll bar is able to reduce the peak of the roll and angular acceleration signals, see e.g. at 42s. Thus, the performances of the entire system (11) are guaranteed.

The required torque $M_{act,ref}$ for the roll dynamics improvement by the high level control is illustrated in Figure 7(c). The changes in ρ_{veh} (Figure 7(d)) guarantee the balance between $\varphi, \ddot{\varphi}$ and $M_{act,ref}$. For example, at 20s the disturbance F_{lat} is around zero, and actuation is unnecessary. Therefore, ρ_{veh} has a low value. At

a high F_{lat} (e.g. 5 – 10s) the signal ρ_{veh} is increased to avoid extremely high $M_{act,ref}$. The operation of the low level control is evaluated based on the torque tracking performance (15), which is guaranteed with an appropriate threshold in most of the simulation. Moreover, the control system satisfies the input constraint i_{limit} , see Figure 7(e). During the actuation of the current, the low level switches to the appropriate LQ control, as shown in Figure 7(f). For example, between 31 – 39s the current i reaches i_{limit} , thus the controller switches to $n = 7$ to avoid limit violation. However, it results in the degradation of torque tracking, see 7(c).

5 CONCLUSIONS

The paper has proposed the design of anti-roll bars based on a hierarchical control architecture. The design is based on the modeling of the chassis and the electro-hydraulic actuator, in which the performance specifications and the uncertainties are formed. In the high level the gain-scheduling LQ control is applied to design actuator torque and improve chassis roll dynamics. In the low level a constrained LQ control is applied to generate actuator torque, while the input limitation is taken into consideration. Within the hierarchical structure the interaction between the two levels is handled. The simulation example shows that the control system improves roll dynamics and handles the input constraint simultaneously.
