27 **Abstract**

28 The Iharkút vertebrate locality, an open-pit mine in the Bakony Mountains (western  
29 Hungary), has provided a rich and diverse assemblage of Late Cretaceous (Santonian)  
30 continental vertebrates. The isolated and associated remains represent 31 different taxa  
31 including fish, amphibians, turtles, lizards, pterosaurs, crocodylians, non-avian dinosaurs and  
32 birds. Sedimentologic investigations suggest that the Iharkút depositional environment was  
33 represented by the floodplain of a very low-gradient river. The 10-50 cm thick bonebed of site  
34 SZ-6, is the most important fossiliferous layer in the open-pit mine and analysis of this site  
35 indicates alternating energy conditions during the bone accumulation, which resulted in  
36 fossils of different states of preservation being deposited together. The vertebrate assemblage  
37 of site SZ-6 includes three main different subsets with widely different taphonomic history.  
38 The characteristics and the preservation mode (high rate of abrasion and the spherical shape)  
39 of the “bone pebbles” suggest that this type of the isolated bones was more exposed to  
40 abrasion and probably the remains were transported from farther away than the other isolated  
41 bones. The second group includes 88% of the Iharkút collection, containing most of the  
42 identified isolated bones and teeth, and represents polytypic attritional remains transported  
43 and deposited by high density flow during ephemeral flood events. Meanwhile the  
44 monospecific ankylosaur skeletal material from Iharkút site SZ-6 may represent a mass death  
45 assemblage because seven skeletons of *Hungarosaurus* were discovered from an area of  
46 approximately 400 m<sup>2</sup> and in many cases close to each other in the same layer. The Iharkút  
47 vertebrate assemblage is dominated by bones of aquatic/semi-aquatic animals, while the  
48 number of terrestrial animal remains is subordinate. The taphonomic analysis of the  
49 ankylosaur material from Iharkút locality further strengthens the previously suggested  
50 hypothesis that some of the ankylosaurs preferred wetland habitats (e.g. areas along fluvial

51 systems) while the other two herbivorous dinosaur groups from Iharkút (ornithopods and  
52 ceratopsians) were probably living in distal habitats.

53

## 54 **1. INTRODUCTION**

55 Vertebrate taphonomy is a relatively young discipline within paleontological  
56 investigations and initially has been focused on Tertiary mammal assemblages (e.g. Voorhies,  
57 1969; Shotwell, 1955; Behrensmeyer, 1975; Shipman, 1981; Badgley, 1986a,b; Weigelt,  
58 1989; Badgley et al., 1995; see also Behrensmeyer et al., 2000 and references therein), and  
59 there were only a limited number of researches which expanded the taphonomic  
60 investigations for vertebrate assemblages of Mesozoic sites (Dodson, 1971; Dodson et al.,  
61 1980; Wood et al., 1988). In the last three decades, many taphonomic investigations were  
62 published related to Mesozoic dinosaur sites of North America (e.g. Rogers, 1990; Fiorillo,  
63 1991; Varricchio and Horner, 1992; Schwartz and Gillette, 1994; Varricchio, 1995;  
64 Carpenter, 1998; White et al., 1998; Ryan et al., 2001; Jennings and Hasiotis, 2006; Britt et  
65 al., 2009; see also Eberth et al., 2007a and references therein), while only a few studies have  
66 been focusing on the Mesozoic dinosaur assemblages of Europe (e.g. Grigorescu, 1983;  
67 Norman, 1987; Sander, 1992; Cook, 1995; Benton et al., 1997; Posmosanu and Cook, 2000;  
68 Pereda Suberbiola et al., 2000; Therrien, 2005; Csiki et al., 2008, 2010; Baele et al., 2012; see  
69 also Eberth et al. 2007a and references therein).

70 Iharkút is a Late Cretaceous (Santonian) vertebrate-bearing locality in the Bakony  
71 Mountains of western Hungary (Fig. 1A), where productive and continuous excavations have  
72 been carried in the last thirteen years (Ősi et al., 2012b). Field work resulted in a very rich and  
73 diversified assemblage of continental animals (i.e. fish, amphibians, turtles, mosasaurs,  
74 lizards, pterosaurs, crocodylians, dinosaurs including birds). The large amount of available  
75 data made necessary a detailed taphonomic evaluation of the vertebrate remains from the

76 Iharkút locality. Approximately 9234 complete and fragmentary bones and 2259 teeth of at  
77 least 31 different taxa have been collected from Iharkút. This abundance and diversity of  
78 fossil taxa plays a significant role in the understanding of the history of European Late  
79 Cretaceous continental vertebrate faunas. Furthermore, due to the palaeogeographic position  
80 (on the Apulian microplate within the western Tethyan archipelago) and the Santonian age of  
81 the locality fills an important gap in the Late Cretaceous record of continental vertebrates in  
82 Europe. Several taxonomic, palaeobiologic and palaeobiogeographic investigations have been  
83 published to demonstrate the diversity and faunalistic relationships of the Iharkút vertebrates  
84 (e.g. Ósi, 2005; Ósi et al., 2005; Ósi and Makádi, 2009; Ósi et al., 2010a,b; Rabi et al., 2011;  
85 Szentesi and Venczel, 2012; Makádi et al., 2012; Ósi et al., 2012a,b; Makádi, 2013a,b).  
86 Taphonomic and palaeoecologic studies of the locality are, however, quite underrepresented.

87         The aim of the present work is to review the taphonomic features of Iharkút vertebrate  
88 assemblage and to interpret the sedimentologic characteristics of the lithofacies units in order  
89 to determine the depositional model of vertebrate fossils. After discussing the geological and  
90 sedimentologic aspects of the locality, we provide an overview of the relative abundance of  
91 vertebrate groups and review the modifications on both the isolated and the  
92 associated/articulated skeletal remains. Finally, we discuss the sedimentologic, taphonomic  
93 and palaeoecological significance of the locality and its fauna, and determine the possible  
94 accumulation circumstances of the isolated bone assemblages and also the skeletal material.

95

## 96 **2. GEOLOGICAL SETTING**

97 The Iharkút locality is situated on an uplifted Mesozoic block of the North Bakony area in the  
98 Transdanubian Range (TR). In Late Mesozoic times the TR was part of the northern segment  
99 of the Apulian microplate between Africa and Europe (e.g. Channell et al., 1979; D'Argenio  
100 and Mindszenty, 1991, 1992). Until after Late Cretaceous times it shared the history of the

101 Eastern Alps (Oberhauser and Bauer, 1980; Mindszenty et al., 1987). Its Triassic carbonate  
102 platforms were drowned in the Early Jurassic when the opening of the Neotethys resulted in  
103 lithospheric extension. In early Cretaceous times extension changed for compression the TR -  
104 sitting on the northern tip of the Periadriatic margin – soon became involved in the  
105 deformation of the Austro-Alpine domain. Thrusting nape movements and the related uplift  
106 resulted in intense erosion and subaerial exposure in this area. In Late Cretaceous times  
107 bauxite deposits formed in those sectors of the exposed carbonate terrains where local  
108 topography provided for relative isolation from coarse-grained clastics. Progressing  
109 deformation resulted in differential subsidence of the previously uplifted areas and bauxites  
110 became covered by clastic sediments eroded from the hinterland (Wagreich, 1988;  
111 Willingshofer et al., 1999). Based on the striking geological similarity of the TR and the  
112 Southern Alps, Kázmér and Kovács (1985) proposed that in its present position the TR was an  
113 “escaped” block having been originally situated in the Alps somewhere in the vicinity of the  
114 present day Drauzug, between the depositional environments of the Northern Calcareous Alps  
115 (Austria) and the Southern Alps (Italy). They suggested that the reason for the eastward  
116 escape was large-scale right-lateral displacement along the Periadriatic lineament in early  
117 Cenozoic times resulted by the convergence of the African and European plates. Cretaceous  
118 bauxites of Austria occurring right below the basal layers of the Late Cretaceous Gosau  
119 sedimentary complex are strikingly similar to Cretaceous bauxites of Hungary supporting the  
120 original juxtaposition of the two areas and corroborating the idea of Kázmér and Kovács  
121 (1985).

122         Though differences between the history of the TR and the Northern Calcareous Alps  
123 became more pronounced only in Tertiary times, subtle differences between the subsidence  
124 histories of the two areas were obvious already as early as in Late Cretaceous times. Bauxites  
125 in the NCA became covered already in Turonian times (Siegl-Farkas and Wagreich, 1996)

126 and accelerated subsidence resulted in the accumulation of thousands of meters of the clastic  
127 Gosau sedimentary complex there, whereas in the TR bauxites remained exposed until after  
128 the early Santonian. Subsidence began later and was much slower here with the thickness of  
129 the Late Cretaceous cover never exceeding 1000 meters (Haas, 2001).

130 The Cenozoic story of the TR consists of flexural deformation in early Palaeogene times  
131 followed by repeated events of strike-slip faulting at various scales and of various  
132 geodynamic controls. In the Miocene, as a result of overall, extension related subsidence of  
133 the wider surroundings, also the TR became partly submerged. This was the time of the  
134 establishment of the Pannonian basin, a Neogene structure formed as a result of large scale  
135 extension and attenuation of the lithosphere in the areas surrounded by the Carpathians  
136 (Royden and Horváth, 1988). In latest Cenozoic times compression resumed and basin  
137 inversion began. Erosion of the uplifting sectors (like the TR) resulted in exhumation of the  
138 Mesozoic and Cenozoic basement. Iharkút is one of those uplifted blocks where a typical  
139 Mesozoic- Cenozoic succession with a major regional unconformity and the related bauxites  
140 between the eroded surface of Late Triassic dolomites and their Late Cretaceous and  
141 Cenozoic cover are exposed at the actual surface.

142

## 143 **2.1. Local geology**

144 The oldest rocks in the Iharkút open-pit mine are Upper Triassic shallow marine  
145 dolomites (Main Dolomite Formation) the irregular karstified surface of which was filled by  
146 bauxite (Nagytárkány Bauxite Formation) during the Upper Cretaceous (pre-Santonian) as a  
147 result of subaerial exposure (Gellai et al., 1985) (Figs. 1B and C). Bauxite and dolomite are  
148 unconformably overlain by the Late Cretaceous Csehbánya Formation, which is rich in both  
149 plant and vertebrate fossils. The Csehbánya Formation is a typical alluvial, flood-plain unit  
150 consisting mainly of fine-grained siltstones and mudstones with several paleosol horizons and

151 crosscut by shallow channel fill sandstones (Tuba et al., 2006; Ósi and Mindszenty, 2009;  
152 Botfalvai et al., 2012).

153 Higher up in the stratigraphic sequence Middle Eocene (Lutetian) conglomerates and  
154 limestones unconformably cover the Csehbánya Formation. The youngest deposit exposed in  
155 the open-pit mine is Pleistocene loess which forms a discontinuous blanket over most of the  
156 area (Fig. 1C).

157

## 158 **2.2. Lithofacies and depositional environment of the Csehbánya Formation**

159 The Csehbánya Formation at the Iharkút locality is built up mainly by overbank fines  
160 (about 80% of all the alluvial complex). Sandstones and conglomerates are subordinate in the  
161 exposed section. The absence of desiccation cracks, the subordinate amount of secondary  
162 (pedogenic) carbonate accumulation and the floral association (subtropical floodplain forest  
163 vegetation; Bodor et al., 2012) show that the climate was dominantly humid, however, with  
164 occasional flash-flood like episodes suggesting some seasonality (Ósi and Mindszenty, 2009).  
165 The deposition of the Csehbánya Formation started in the Santonian (*Oculopollis-*  
166 *Complexiopollis* Zone; Siegl-Farkas, 1991) confirmed also by palaeomagnetic studies (Szalai,  
167 2005).

168 The age of bonebed at site SZ-6 was examined by palynological methods and resulted  
169 in a more accurate age showing that the age of the bone accumulations (Bodor and Baranyi,  
170 2012) is equivalent to the Santonian *Oculopollis zaklinskaiae–Tetracolporopollenites*  
171 (*Brecolpites*) *globosus* Zone.

172

### 173 *2.2.1. Floodplain deposits*

174 *Description:* The fine siltstones and mudstones are organized into more-or-less  
175 regular, meter- to two-meter thick, paleosol-capped alluvial cycles interrupted by occasional

176 shallow (2 to 3 m deep 30 to 60 m wide) fine-grained sandstone bodies and thin (0.5 to 1 m)  
177 fine-grained sheet sandstones. The abundance and depth of such cross-cutting channel  
178 forming sandstone-bodies and sandstone-blankets increase upwards. Coarse sandstones and/or  
179 conglomerates are rare, the latter always restricted to the channel-forming sandstone bodies.  
180 Tabular- or through cross-bedding is likewise rare. There are no desiccation cracks, and even  
181 secondary carbonate accumulation is not apparent (observable in thin sections only) in the  
182 paleosols, however, smaller or larger ripped-up clayclasts are abundant at the base of some of  
183 the channels. Three major types of paleosols could be distinguished: (a) reddish, slightly  
184 calcareous, moderately developed, well-drained 30 to 100 cm thick paleosols with vertical  
185 root traces (and burial-gley features), situated – as a rule – in the lower part of the open-pit  
186 (b) thick (> 100 cm), however, weakly developed, pale, yellowish paleosols with purple to  
187 violet coloured gleyed spots and abundant root-mottles, predominant in the upper section of  
188 the open pit (Fig. 1C), (c) > 100 cm thick, pale yellowish to grey very weakly developed  
189 paleosols with tiny irregular root traces. On top of the channel fills (e.g. site SZ-6), and at the  
190 lower segment of the open pit such as site SZ-7-8 (see below) fine-grained dark grey siltstone  
191 layers are abundant

192 *Interpretation:* The discrete well-drained reddish paleosol horizons encountered  
193 exclusively in the lower 20 meters of the exposed cover sequence are products of subaerial  
194 exposure in a relatively high-level floodplain environment. Most paleosols, however, abound  
195 in hydromorphic features (gley-spots) and thus point to either occasional or - particularly in  
196 the upper part of the exposed thickness – permanent water-logging which may be interpreted  
197 as a low-level flood-plain position for the sedimentary environment. They are also mostly  
198 aggradational (i.e. “cumulate” sensu Wright and Marriott (1996)) reflecting an alluvial  
199 sedimentary regime keeping pace with the steady subsidence of the area. The fine-grained  
200 dark-grey (organic rich) layers occurring also in these upper levels, particularly on top of the

201 coarser-grained channel-forming sandstone bodies are interpreted as flood-plain ponds and/or  
202 abandoned channels (Tuba et al., 2006; Ósi and Mindszenty, 2009).

203

### 204 2.2.2. Channel-filling deposits

205 *Description:* Channel-fill deposits can be divided into at least three lithotypes in the  
206 Iharkút open-pit mine based on their lithofacies, geometry and palaeontology.

207 The first group includes lenticular sandstone ribbons max. 2 to 3 m thick and 30 to 60  
208 m wide. They are the most frequent fluvial units exposed in the open-pit (Fig. 1C) and  
209 predominantly composed of fine- to medium-grained sandstone, although smaller or larger  
210 ripped-up clayclasts (0.3-2 cm in diameter) of the floodplain-fines are also abundant at the  
211 base of some of the channels (e.g. SZ-1 and SZ-6 sites; Figs. 2 and 3). Grain size decreases  
212 upwards and bioturbation (root traces) occasionally appears at the top of these channel bodies.  
213 The lower surface of these beds is clearly erosional, cutting into the floodplain deposits. Point  
214 bar accretion is absent and cross-bedding is very rare in the channel fills. They contain plant  
215 debris and bone fragments occasionally in large quantities (e.g. SZ-1 and SZ-6 sites), but  
216 coarse sandstone and conglomerates are rare (Ósi and Mindszenty, 2009). These types of  
217 channel sandstones are typically isolated from one another laterally. The lenticular sandstone  
218 bodies have a homogeneous texture because both tabular and through cross-bedding is very  
219 rare.

220 The second group consists of tabular sandstone bodies with flat, non-erosional base.  
221 Their thickness is usually limited to a few meters (0.5–1.5 m) and they are more extensive  
222 laterally than the sandstone bodies of the first group. The tabular sandstone bodies are more  
223 frequent in the upper part of the exposed thickness. They predominantly consist of finer  
224 grained sandstones than the lenticular sandstones, and contain only scattered plant debris,  
225 while the bones are generally missing (in the studied strata). Fining-upward trends are

226 common and the top of the sheets is grading into pedogenically modified siltstone. Tabular or  
227 through cross-bedding and ripped-up clayclasts are very rare.

228         The third group includes conglomerates and sandstone channel fills restricted mainly  
229 to the uppermost part of the exposed thickness. The lower surface of such beds is clearly  
230 erosional, they cut into the floodplain deposits. The conglomerate horizons are often  
231 interrupted by sandstone, and this alternation repeatedly appears in the conglomerate filling  
232 sequences. Lateral accretion was present, since cross-bedding is discernible in the channel  
233 fills. The presence of this type of fluvial sediment is very limited in the open pit mine (only  
234 two occurrences recorded) and bones and plant debris are completely absent from these  
235 channel fills.

236         *Interpretations:* Since the lenticular sandstone bodies, occurring at various  
237 topographic levels, are clearly isolated from each other they can be interpreted as  
238 anastomosing river deposits (Makaske, 2001; Roberts, 2007; Ósi and Mindszenty, 2009).  
239 Furthermore, the low width/depth ratios, the relatively homogenous internal texture  
240 (infrequent cross-bedding), and the grain size ranges (from coarse clayclasts to fine sand; Fig.  
241 3) are also characteristic features of the anastomosing rivers (Makaske, 2001). The tabular  
242 sandstone sheets may be interpreted as crevasse-splay deposits or sheet splays which are  
243 likewise commonly associated with anastomosing river systems (Miall, 1996; Makaske, 2001;  
244 Makaske et al., 2002; Roberts, 2007). The term anastomosing is identified here by the  
245 presence of multiple, vertically aggraded sandstone ribbons (Eberth and Miall, 1991), which  
246 can be interpreted as “interconnected channels that enclose floodbasins” (Makaske,  
247 2001:149). The characters of the lenticular channels (stable banks, multiple-story bodies) and  
248 the abundant crevasse-splay deposits observed in the Iharkút open-cast mine might suggest  
249 that seasonal flooding and substantial vertical aggradation of the floodplain were common

250 indicating high rate of sediment accumulation (i.e. high rate of subsidence, see also above)  
251 (Roberts, 2007) for the Csehbánya Formation.

252

### 253 **2.3. Description of the depositional environment of the bonebeds in the Iharkút mine**

254 Three different stratigraphic units of the Csehbánya Formation contain bones in  
255 Iharkút, these are exposed in 8 different sites (SZ-1–SZ-8) within the open-pit mine. The SZ-1  
256 site is in the northern part of the mine and a few hundred poorly preserved fossils have been  
257 collected from here. The sites SZ-2–SZ-6, corresponding to the localities that yielded six  
258 *Hungarosaurus* skeletons and most of the isolated bones used in this study, are  
259 stratigraphically equivalent and relatively close to each other, so the name SZ-6 is here  
260 applied for all of these sites (see Ósi et al., 2014 for the position of site Sz-6 at Iharkút mine).  
261 Sites SZ-7-8 are two outcrops of a dark grey, silt and clay bed rich in organic matter that  
262 contains coalified plant remains and a rich assemblage of microvertebrates. Though bones can  
263 be found essentially all over the area of the open-pit mine, bone accumulation is most  
264 significant in the sites SZ-1, SZ-6 and SZ-7-8 (Figs. 2–4). However, the taphonomic  
265 investigations were restricted only to the material collected from the site SZ-6, because the  
266 amount of material from site SZ-1 is not sufficient for detailed investigations (amounting less  
267 than the 1% of the entire Iharkút assemblage), while the remains from sites SZ-7-8 are limited  
268 for microvertebrates which have different taphonomic history (Dodson, 1973; and see later in  
269 this text). Nevertheless, we felt it necessary to describe the other bonebeds in the Iharkút  
270 mine, as well, because their presentation contributes to our understanding of the bone  
271 depositional modes in the locality. We use the term bonebed as “relative concentration of  
272 vertebrate hardparts preserved in a localized area or stratigraphically limited sedimentary unit  
273 and derived from more than one individual” (Eberth et al., 2007a:3).

274

### 275 2.3.1. Site SZ-1

276 *Description:* The site SZ-1, situated in the northern part of the open-pit, was the first  
277 exposure where vertebrate remains were found and the area was recognized as a potential  
278 Cretaceous vertebrate locality (Ősi, 2004). The bonebed of site SZ-1 is a 20 to 30 cm thick  
279 yellow sandstone which contains bone fragments, teeth, plant debris, and ripped up clayclasts  
280 at the base of the bonebed (Fig. 2). The base of this layer is erosional, it cuts into the  
281 underlying yellow clay stone layer. The bones can be found in the basal breccia as well as in  
282 the immediately overlying medium-grained sandstone layer. The grain size of the sequence is  
283 fining upward and it is homogeneous in texture, neither tabular or through cross-bedding nor  
284 lateral accretion were detected at this site. The vertebrate remains found at this site are less  
285 than the 1% of the whole Iharkút assemblage.

286 *Interpretations:* Section SZ-1 can be characterized first by increasing energy  
287 conditions, followed by energy decrease after the accumulation of the bonebed (Fig 2). The  
288 site was interpreted as a ribbon channel, because the lateral erosion was limited and  
289 width/depth ratios are low (Botfalvai et al., 2012).

290

### 291 2.3.2. Site SZ-6

292 *Description:* The site SZ-6 is the most important bone accumulation in the Iharkút  
293 locality because of the high abundance of vertebrate remains; approximately 80% of the  
294 complete specimens were discovered here. Most of the vertebrate fossils were recovered from  
295 an approximately 3 m thick sequence of beds made up of coarse-grained, sandstone and  
296 organic-rich siltstone (Fig 3). The basal surface of the sequence is clearly erosional, it cuts  
297 into the underlying green-clay stone layer. The lowest bonebed in SZ-6 is a 10 to 50 cm thick  
298 basal breccia composed of grey sandstone, siltstone, clayclasts, pebbles and plant debris (Fig.  
299 3A) that occasionally contains complete or, more frequently, fragmentary bones. The basal

300 breccia presents a clear tendency of fining upwards. This sequence with poorly sorted coarse  
301 sandstone breccia overlain by finely laminated siltstone is repeated several times (Fig. 3B)  
302 resulting in a stacked series of fining upward units. The clayclasts in the basal breccia are  
303 poorly sorted varying between 0.3 to 2 cm in diameter and occasionally even with a few cm-  
304 sized dolomite pebbles scattered among the clayclasts. This most important fossiliferous layer  
305 is covered by a sandstone bed also containing scarce remains of vertebrate fossils. The  
306 uppermost bed of this succession is a 30 to 50 cm thick, laminated, greyish siltstone which  
307 contains plant debris, fewer bones but yielded incomplete skeletons of *Hungarosaurus* (see  
308 below). Vertebrate fossils are common in the coarse-grained, poorly sorted deposits of the  
309 lower part of sequence SZ-6, while they are only rarely encountered in the upper laminated  
310 deposit.

311 *Interpretation:* The basal erosional surface of the sequence, together with the  
312 overlying smaller or larger ripped-up clayclasts of floodplain origin indicate high-energy  
313 conditions associated with rapid flooding events resulting in the efficient reworking of the  
314 material from the interfluvial areas (Tuba et al., 2006; Ósi and Mindszenty, 2009). The  
315 depositional environment was probably that of a high density (flash) flow because: (1) The  
316 transported sediment is poorly sorted, clasts ranging from few cm-sized dolomite pebbles to  
317 medium-grain sand often with several meters long tree trunks deposited together within the  
318 basal breccia layer (Ósi and Mindszenty, 2009). (2) Absence of unidirectional, hydraulic-  
319 flow-generated sedimentary structure, but occurrences of the clay laminae sign that the  
320 massive sedimentary fabric of this deposits is primary and not the results of bioturbations or  
321 other postdepositional events (such as Eberth et al., 2006). (3) The highest bone concentration  
322 occurs at the base of the unit (basal breccia layer) and are poorly sorted (see below at the  
323 taphonomic section). (4) The bones and tree trunks show little evidence of preferred  
324 orientation and some elements have very high dip angles (such as Eberth et al., 2006). Energy

325 conditions at site SZ-6 were, however, not constant because deposition of the basal breccia  
326 was interrupted several times by that of quiet water deposits (silty-sandstone and clay)  
327 particularly during the deposition of the lower part of the succession (Fig. 3B). The  
328 depositional environment characterized by these alternating energy conditions provided for  
329 the accumulation of bones of highly different states of preservation in the same bed (isolated,  
330 associated and even articulated skeletal remains were found together in the basal breccia  
331 horizon; see below). The fining upward sequence covering the basal important fossiliferous  
332 layer indicates reductions in flow velocity, either when the channels were abandoned or  
333 possibly at the end of the flood events (Botfalvai et al., 2012). Site SZ-6 is interpreted as one  
334 of the abandoned channels formed during these (ephemeral) flood events (Ősi and  
335 Mindszenty, 2009). Incised and subsequently suddenly abandoned channels are common  
336 structures associated with anastomosing systems in low-level floodplain environments,  
337 because they can be created by the process of avulsion as the river compensates for the  
338 aggradation or plugging of individual channels during the flood events (Behrensmeyer, 1988;  
339 Smith et al., 1989; Eberth and Miall, 1991; Aslan and Behrensmeyer, 1996; Miall, 1996;  
340 Makaske, 2001; Makaske et al., 2002; Roberts, 2007).

341

### 342 2.3.3. SZ-7-8 site

343 *Description:* The bonebed of the SZ-7-8 site is a 10 to 20 cm thick, dark grey, siltstone  
344 and clay bed rich in organic matter (Fig. 4), containing mainly larger fragments of coalified  
345 tree trunks and twigs, plant meso- and microfossils, microvertebrates and rarely larger  
346 fragmentary bones. Furthermore, 1 to 3 mm sized amber fragments and a large number of  
347 pyritized mollusc shells have been also collected. This bonebed consists mainly of skeletal  
348 elements of fish, albanerpetontids, anurans, turtles, squamates, crocodylians and dinosaurs

349 (Szentesi and Venczel, 2010, 2012; Ósi et al., 2012b). The microfossil bonebed is sandwiched  
350 between two medium grained sandstone layers (Fig. 4).

351 *Interpretation:* The presence of hydromorphic paleosol horizons above and below the  
352 sequences (Fig. 4) may indicate that the studied area was part of the low-level floodplain  
353 characterized by overall hydromorphy. Furthermore, the fossiliferous layers also show clear  
354 signs of hydromorphy and low energy conditions indicating that these were probably a small-  
355 scale stagnant pools of the floodplain filled up by organic-rich sediments (Botfalvai et al.,  
356 2012; Ósi et al., 2012b). They are typical microfossil bonebeds sensu Eberth et al. (2007a),  
357 because these are concentrated deposits of bones of several individuals in a stratigraphically  
358 well-limited sedimentary units within which the dimension of the bioclasts (bones and teeth)  
359 does not exceed 5 cm.

360

361

### 362 **3. METHOD OF INVESTIGATION**

363 All fossil remains from Iharkút are housed in the collection of the Hungarian Natural  
364 History Museum (MTM) in Budapest. The examined material was collected from 2000 to  
365 2012. Iharkút, as a Late Cretaceous continental vertebrate site, was discovered in 2000 and  
366 ever since then annually a two or three weeks long field work has taken place at the locality.  
367 The first excavations started at the site SZ-1, then from 2003 fieldwork continued at site SZ-6.

368 Furthermore, several tons of sediment has been collected from sites SZ-6 and SZ-7-8  
369 for screenwashing, from which 20% was the potentially fossiliferous fraction. Three mesh  
370 sizes were used for screenwashing, of which the 1 mm size proved to be the most favourable  
371 for the extraction of microvertebrates.

372 Basic taphonomic investigations began in 2008 when careful documentation of the  
373 taphonomic features started both at the excavation sites and on the previously collected

374 material. Taphonomic investigations were confined to the entire macrofossil material  
375 (following Behrensmeyer et al. (1979), macrofossil assemblages consisting of bones of  
376 animals whose body weight was over 1 kg). However, investigation of taxon diversity was  
377 also extended to include those taxa which were known exclusively from microvertebrate  
378 assemblages, (e.g. amphibians and small squamates), because the presence of these taxa  
379 provided important information about the studied palaeocommunities.

380         During the taphonomic investigation each bone was examined to determine its  
381 osteological and taxonomic identity wherever it was possible. In addition, any taphonomic  
382 modification feature of the bone surfaces (i.e., weathering, abrasion, breakage pattern, etc.)  
383 was documented. Bone morphology, state of preservation and the deformations observed on  
384 the specimens have been summarized in Supplementary Information 1. We have followed  
385 mostly the methods described by Pereda Suberbiola et al. (2000) in order to gather all the  
386 taphonomic information about the fossil remains. Pereda Suberbiola et al. (2000) built a  
387 useful database using previous works (e.g. Behrensmeyer, 1978, 1991) that includes the most  
388 important quantitative and qualitative taphonomic features of the fossil material. Furthermore,  
389 we extended the database of Pereda Suberbiola et al. (2000) with additional characters (e.g.  
390 maximum dimension of bones after the fragmentation, number of epiphyseal regions of limb  
391 bones, and presence of pyrite crust on the bone surface).Data were collected in the “Iharkút  
392 taphonomic dataset” file (See Supplementary Information 2) that includes all characters of the  
393 examined bones.

394

#### 395 **4. TAXONOMIC COMPOSITION**

396

397         In general, the Santonian Iharkút vertebrate fauna shows a composition basically  
398 similar at family level to other Late Cretaceous continental vertebrate faunas of Europe (see

399 e.g. Buffetaut and Le Loeuff, 1991; Allain and Pereda Suberbiola, 2003; Weishampel et al.,  
400 2010). Nevertheless, at generic and species level, numerous differences have been  
401 documented (Ősi et al., 2012b), which, among other factors, further support the insular  
402 evolution of the Iharkút continental fauna within the European archipelago (Ősi et al., 2012b).

403 The isolated and associated remains represent 31 different taxa including fish,  
404 amphibians, turtles, lizards, pterosaurs, crocodylians, non-avian dinosaurs and birds (detailed  
405 taxon list of the Iharkút fauna, see Table 1).

406

## 407 **5. VERTEBRATE MATERIAL OF IHARKÚT**

408

409 Currently the complete vertebrate material collected from the Csehbánya Formation at  
410 Iharkút contains 9222 bone and bone fragments and 2271 isolated teeth based on “Iharkút  
411 taphonomic dataset” (see Supplementary Information 2 and Table 2). Of these vertebrate  
412 remains, 7475 items (isolated macro- and microvertebrates, teeth and bones, associated and  
413 articulated skeletal elements) were identified osteologically and taxonomically. 9099 bones  
414 and fragments were discovered at site SZ-6 from an approximately 400 m<sup>2</sup> area excavated  
415 during the last ten years, and indicate that the bonebed has a concentration of close to 23  
416 bones (fragments)/m<sup>2</sup> at site SZ-6 (based on “Iharkút taphonomic dataset”). This is a  
417 relatively high bone concentration compared with the bonebeds of various dinosaur sites (e.g.  
418 Fiorillo, 1991; Varricchio, 1995; Pereda Suberbiola et al., 2000; Gates, 2005; Britt et al.,  
419 2009; Fiorillo et al., 2010).

420

### 421 **5.1. Isolated bones**

422 We follow the interpretation of Badgley (1986a) considering that as long as there is no  
423 evidence for the probability of association among the vertebrate remains, all of the elements  
424 should be regarded as separated and isolated elements.

425 Most of the bones discovered in the bonebeds of the Iharkút locality are isolated  
426 specimens. The high number of disarticulated and isolated bones suggests the presence of  
427 dispersal processes during the accumulation of vertebrate remains (Hill, 1979; Hill and  
428 Behrensmeyer, 1984; Coard and Dennell, 1995; McNamara et al., 2012). The isolated bone  
429 assemblages can be divided into four different groups (Fig. 5 A-D), these subsets have widely  
430 different taphonomic histories (Table 2).

431 - The first subset is built up of the highly abraded, small-sized, rounded “bone  
432 pebbles” which are unidentified taxonomically and/or anatomically (Fig. 5A).

433 -The second group consists of well- and medium-preserved, identified isolated bone  
434 elements, and represents one of the most important taphonomic subjects (Fig. 5B).

435 -The third subset contains “complex”, co-ossified skeletal elements such as skulls,  
436 mandibles (Fig. 5C and D), as well as the synsacra of ankylosaurs and a rhabdodontid  
437 dinosaur. These are not considered here as partial skeletons (contra Csiki et al., 2012),  
438 because they can be regarded as a single ossified unit in the original skeleton and therefore  
439 can be preserved together in many cases (Hill, 1979; Hill and Behrensmeyer, 1984; Dodson  
440 1971). As, for instance, the limb elements are connected along a joint surface (easily  
441 separable) and hence the preservation of association of those elements is limited, thus they are  
442 considered as a partial skeleton if found in associated position. These “complex” isolated  
443 skeletal elements (Fig. 5C and D) are rare in the assemblages and their occurrence is confined  
444 to the layers of the SZ-6 site. Separation of this category within the isolated bones group is  
445 justifiable, because completely preserved skulls and mandibles are very rare (usually only  
446 separated parts of these bones are found, e.g. frontal, articular, dentary, etc.) and they are

447 confined to just a few taxa (*Foxemys*, *Iharkutosuchus*, *Hungarosaurus*, *Mochlodon*,  
448 *Bakonydraco*). Furthermore, the taphonomic history of “complex” isolated skeletal elements  
449 may be different from that of the separated elements of the skull and mandibles (Boaz and  
450 Behrensmeyer, 1976). The fourth subset in this category consists of the isolated teeth.  
451 Distinction of tooth remains from the other groups of isolated bones is reasonable, because the  
452 dispersal potential of teeth is probably different from that of the bones at the same current  
453 velocity, therefore the mode of accumulation of teeth is different from that of other fossils  
454 (Behrensmeyer, 1975; Fiorillo, 1991). Furthermore, the resistance of teeth against the  
455 abrasion is different from that of other fossils, because the enamel-coated teeth are more  
456 durable in transport environments than bones (Argast et al., 1987).

457

458

## 459 **5.2. Associated and articulated bone assemblages**

460

461 The disarticulated but associated skeletal elements are rarer than the isolated bones,  
462 and it seems that these are limited to only certain horizons of SZ-6 site and only to one taxon  
463 (Table 2 and Fig. 5E). All of the six associated skeletons belong to *Hungarosaurus*  
464 (Ankylosaur) and were discovered at SZ-6 site (Ősi, 2005; Ősi and Makádi, 2009).

465 There is only one *Hungarosaurus* skeleton in the collection from Iharkút which is  
466 preserved in an articulated position (Table 2; Fig 5F). It was found in the basal breccia of the  
467 SZ-6 site. This skeletal segment includes both ilia, ischia, the co-ossified synsacrum region  
468 with the ossified ribs in articulation. All elements were preserved in their original anatomical  
469 position, thus the partial skeleton is regarded as articulated (Badgley, 1986a).

470

## 471 **5.3. Microvertebrate assemblages**

472

473           According to Behrensmeyer et al. (1979) microvertebrate assemblages consist of  
474 bones of animals whose body weight was <1kg (Table 2). All of the microvertebrate elements  
475 are isolated bones from the SZ-7-8 and the SZ-6 sites and most of them were collected by  
476 screenwashing (Szentesi and Venczel, 2010, 2012; Makádi, 2013a,b). We refer to microfossil  
477 remains only where necessary; the detailed taphonomic investigation of the microfossil  
478 assemblage is not the subject of the present paper, because they have a different taphonomic  
479 history (Dodson, 1973; Behrensmeyer, 1991; Pereda Suberbiola et al., 2000).

480

#### 481 **5.4. Discussion**

482

483           The wide range of taphonomic modes (isolated, associated and articulated  
484 preservation) represented within the same vertebrate-bearing lithofacies units suggests that  
485 there were variations regarding both the bone sources and the transportation histories of the  
486 individual bones at site SZ-6 in the Iharkút mine. The isolated vertebrate elements (all of the  
487 four subsets) represent a multispecific (or multitaxic/multidominant) assemblage  
488 (Behrensmeyer, 2007; Eberth et al., 2007a), while the other two main preservation modes,  
489 associated and articulated skeletal material, are restricted to only one taxon (*Hungarosaurus*),  
490 indicating a significantly different taphonomic (and palaeoecological) history for these  
491 ankylosaur remains.

492

493

#### 494 **6. FOSSIL ASSEMBLAGE DATA AND TAXONOMIC ABUNDANCES**

495

496 Many archaeological and paleontological investigations employed estimates of  
497 abundances of taxa in mammalian (e.g. Shotwell, 1955; Gilinsky and Bennington, 1994;  
498 Lyman, 1994a,b; Badgley, 1986a,b) and reptilian (e.g. Fiorillo, 1991; Varricchio, 1995; White  
499 et al., 1998; Pereda Suberbiola et al., 2000; Eberth et al., 2007b; Britt et al., 2009.)  
500 assemblages. This kind of taphonomic investigations are of crucial importance to deduce  
501 ecological conclusions.

502

### 503 **6.1. Number of identified specimens (NISP)**

504

505 *Method:* The number of identified specimens is the most popular and simplest measure  
506 of taxonomic abundances and therefore it is commonly used by palaeontologists (e.g.  
507 Varricchio, 1995; Pereda Suberbiola et al., 2000; Alberdi et al., 2001; Britt et al., 2009;  
508 Cannon, 2012). The NISP value includes the number of bones, teeth and fragments which  
509 were taxonomically identified as skeletal elements at least at order level (Lyman, 2008) in the  
510 Iharkút vertebrate assemblages. This method has not been used on the associated and  
511 articulated skeletal elements because they are proven as being separate individuals, unlike the  
512 isolated bones (see below).

513 *Result:* The total NISP value of the Iharkút remains was 6871 based on isolated bones  
514 and teeth (including macro- and microvertebrates). The  $NISP_i$  (where  $i$  signifies a particular  
515 taxon) was determined for each taxon in order to estimate the frequency differences among  
516 taxa in the studied material (Table 3). The taxon diversity calculation based on NISP shows  
517 that turtle and dinosaur remains represent more than half of the identified elements (Fig. 6A).  
518 Crocodylians are the third most common group while the amount of fossils of *Pannoniasaurus*  
519 and fish are about approximately equal in the Iharkút assemblages. The amphibian taxa  
520 represent about 4% of the NISP of the Iharkút collection (Fig. 6A).

521           *Comments:* Our results show that taxa with a high number of resistant and frequent  
522 osteoderms (ankylosaurs, turtles) are the most abundant in the assemblage (Table 3). This fact  
523 may distort rates of frequency of taxa because taxa with osteoderms will be overrepresented  
524 compared to other forms. This problem was also observed by several authors, namely that  
525 NISP varies intertaxonomically, because different taxa may have different number of bones  
526 and teeth (White, 1953; Ringrose, 1993; Lyman, 2008; Britt et al., 2009; Moor and Norman,  
527 2009; Domingo et al., 2013). Furthermore , the fragmentation increases the NISP value (for a  
528 while) because fragmentation creates more pieces from one bone and therefore the  
529 fragmentation rate of the bone assemblage significantly affects the NISP value (the  
530 fragmentation rate is calculable if  $NISP_i$  is divided by  $MNI_i$ , where  $i$  signifies a particular  
531 taxon; Cannon, 2012). The vertebrate remains of Iharkút also show relationship between  
532 NISP and bone fragmentation (Table 3).

533

## 534 **6.2. Minimum number of individuals (MNI)**

535

536           Various methods are used to determine the minimum number of individuals (MNI) in  
537 vertebrate assemblages and different assessments can introduce problems when several  
538 assemblages are compared by their MNI (Horton, 1984; Turner and Fieller, 1985; Pereda  
539 Suberbiola et al., 2000; Domingo et al., 2013). Therefore we discuss the details of the  
540 calculation process of minimum number of individuals which was applied here for the Iharkút  
541 vertebrate remains.

542           *Method:* During the calculation of MNI, at first we determined the minimum number  
543 of elements (MNE) for the most common skeletal elements of a taxon, then the greatest MNE  
544 value was defined as an MNI value for that taxon (White, 1953; Badgley, 1986a; Lyman,  
545 1994b; Moor and Norman, 2009). The MNE value is represented by a minimum number of a

546 particular skeletal element of a taxon, for example, the left femur, left dentary, or the skull  
547 (Grayson and Frey, 2004; Lyman, 2004a, 2008). The MNE value was determined only for the  
548 accurately definable skeletal parts of all taxa. In cases when accurate anatomical position of  
549 the element was not determinable (e.g. ribs, vertebrae, limb bone fragments), the MNE value  
550 could not be calculated. The MNI values for each taxa were defined by the most frequent  
551 diagnostic skeletal part whose accurate anatomic position (e.g. left or right side of the body)  
552 was well defined. The advantage of this method is that it minimizes the chance of the same  
553 element being counted twice, which is the principle of MNI and MNE (Ringrose, 1993).  
554 However, this method ignores age (e.g. juvenile or adult) and size factors and this bias  
555 potentially increases or decreases the MNI value for a particular taxon. Furthermore we  
556 considered the six associated and one articulated skeletal remains as different seven  
557 individuals in the Iharkút remains during the MNI calculation (Table 3).

558 *Result:* A minimum of 218 individuals including fish, amphibians, reptiles and birds  
559 were identified in the Iharkút vertebrate assemblage (Table 3). The taxon diversity calculation  
560 based on MNI shows that pterosaurs, amphibians and fish are the most abundant taxa in the  
561 Iharkút assemblage while dinosaurs and turtles are rarer (Table 3 and Fig. 6B).

562 *Comments:* The MNI values show different distribution of taxonomic abundances  
563 from that was indicated by NISP. Taxa whose bones are rare in the observed material show  
564 relatively high MNI value, while taxa which have rich bone remains in the Iharkút assemblage  
565 were underrepresented by MNI. The difference is explained by correlation between MNI and  
566 NISP (Lyman, 2008):

567 (1) Fragmentation increases the NISP value of a taxon but the MNI does not increase  
568 with NISP because the MNI depends on the anatomical and taxonomical features of elements  
569 and not the number of bone fragments (Turner and Fieller, 1985; Ringrose, 1993). As Lyman

570 (2008:46) concluded “MNI values exaggerate the importance of rarely represented taxa, or  
571 taxa represented by low NISP values”.

572 (2) Material representing certain rare taxa includes a large number of bones, all of  
573 which are defined as single individuals. For instance, pterosaurian remains contain 58  
574 symphyseal regions of the mandible representing 58 different individuals (Ősi et al., 2005;  
575 Prondvai et al., 2014), thus the  $MNI_{pt}$  is 58. On the other hand, turtle material includes a lot of  
576 indeterminable shell fragments (which increase NISP value), but does not represent disparate  
577 individuals (MNI is low). These problems of calculation of MNI introduce several biases and  
578 these should be considered when making comparison of taxonomic abundances of fragmented  
579 assemblages (Moor and Norman, 2009).

580

### 581 **6.3. Skeletal representation**

582

583 The abundance of skeletal elements in a given vertebrate assemblage can be measured  
584 (White, 1953; Shotwell, 1955; Grayson, 1978; Badgley, 1986a,b; Spencer et al., 2003; Britt  
585 et al., 2009; Mannion and Upchurch, 2010; Domingo et al., 2013). The determination of  
586 abundance of skeletal elements has significance in deciding, for instance, whether the bones  
587 of ankylosaurs are more abundant than the bones of other dinosaur taxa either because the  
588 former taxon was originally more abundant in the ecosystem, or there were some agents or  
589 processes of fossil accumulation (e.g. the differing durabilities of bone material, differences in  
590 the pre- or postdepositional taphonomic history of the vertebrate remains) which simply  
591 collected more elements of ankylosaurs than those of other dinosaur taxa (Behrensmeyer,  
592 1975; Kidwell, 2001; Fernández-Yalvo and Andrews, 2003; Lyman 2008).

593

#### 594 *6.3.1. Skeletal completeness*

595

596 We used the measure of Shotwell (1955) of relative skeletal completeness in order to  
597 decide which taxa were members of a community living in proximity to the site of deposition  
598 (and therefore are expected to have died often near it) and which taxa lived in more distant  
599 communities (Shotwell, 1955; Grayson, 1978; Lyman 1994b). The basic assumption is that  
600 taxa from a distant community are expected to show limited percentage of skeletal  
601 completeness because they have lesser probabilities for complete skeletal preservation  
602 (because of carnivore activity, transportation etc.) than the skeletons of those taxa which lived  
603 closer to the site of deposition (Shotwell, 1955; Dodson, 1971).

604 *Method:* We used the following equation for this calculation (Shotwell, 1955; Lyman,  
605 2004b; Britt et al., 2009):

606

$$607 \quad \%R_i = (A_i \times 100) / (E_i \times MNI)$$

$$608 \quad \%TC = (\sum A_t \times 100) / (\sum E_t \times MNI)$$

609

610  $\%R_i$ : percentage of relative proportion of element i in population of MNI

611  $A_i$ : actual number of element i in the collection

612  $E_i$ : expected number of element i in a complete skeleton per individual

613 MNI: minimum number of individuals

614  $\%TC_t$ : percentage of total skeletal completeness of taxon t

615  $\sum A_t$ : actual number of skeletal elements of taxon t

616  $\sum E_t$ : expected number of elements in a complete skeleton of taxon t

617

618 The calculation of skeletal completeness per taxa was restricted to the isolated bone  
619 assemblage of sit SZ-6. The calculation of skeletal representations was not done on the

620 microfossil assemblage (amphibians and small lizards) because they may have a different  
621 taphonomic history. In addition, calculations of skeletal completeness of fish and  
622 *Ajkaceratops* cannot be performed due to limited available information, since the expected  
623 number of elements in their complete skeleton is unknown.

624 *Results:* The total skeletal completeness of the counted eight groups (turtles,  
625 mosasauroids, crocodylians, pterosaurs, ankylosaurs, rhabdodontid ornithopods, non-avian  
626 theropods and avialans) range from 0.47% to 30% (Table 4). Among dinosaurs, ankylosaurs  
627 and theropods show higher skeletal completeness than rhabdodontid ornithopods.

628 *Comments:* Relatively high percentage of the skeletal completeness of the site SZ-6  
629 vertebrate assemblage (most taxa show over 10% of skeletal completeness) may suggest that  
630 the sorting effects were not significant before bone accumulation and that a large proportion  
631 of the individual skeletons was deposited together in a particular place (Table 4).

632

### 633 6.3.2. Bone representation by size

634

635 There is evidence for taphonomic size bias against the small-bodied taxa in most  
636 vertebrate assemblages (Behrensmeyer et al., 1979; Behrensmeyer, 1991; Rogers et al., 2001;  
637 Britt et al., 2009; Brown et al., 2013; Evans et al., 2013). Thus it is essential to investigate this  
638 kind of biases during the palaeoecological analysis.

639 *Method:* At first, we divided the bones of the SZ-6 assemblage into three size  
640 categories according to their dimension at pre-breakage state (small: <5 cm; medium: 5-10  
641 cm; large: 10-50 cm) and then we observed which size category is frequently overrepresented  
642 relative to its expected value (that element was overrepresented where  $\%R_i$  exceeds  $\%TC_t$  in  
643 the dataset of Table 4 based on Britt et al., 2009). The calculation of size bias was not done on  
644 the microvertebrates assemblage (remains of amphibians, small lizards), teeth of sauropsids,

645 and associated and articulated skeletons because these preservational categories have a  
646 different collecting method and taphonomic history (e.g. Coard and Dennell, 1994; Blob and  
647 Fiorillo, 1996).

648 *Results:* The elements of medium and large size categories are frequently  
649 overrepresented (about 40%) while elements of small size are even more frequently  
650 underrepresented (about 90%), regardless of taxonomic status (Fig. 7) at SZ-6 assemblage.  
651 This distribution indicates a direct correlation between bone size and abundance.

652 *Comments:* There are several explanations for commonly observed bias against small-  
653 bodied taxa, for instance, biological and physical degradation; biases of collection and  
654 taxonomy or fragmentation rate of the bone assemblage (Behrensmeyer et al., 1979;  
655 Behrensmeyer, 1991; Benton, 2008; Britt et al., 2009; Mannion and Upchurch, 2010; Brown  
656 et al., 2013; Evans et al., 2013). In the SZ-6 assemblage probably the collecting method  
657 contributed to the bias because the field methods are not favourable for small bones. The  
658 small bones and fragments are more difficult to recognize and collect than larger ones during  
659 excavation. The detected taphonomic size sorting may be caused by collecting bias, and may  
660 not be the consequence of transportation sorting. However, the size biases should be  
661 considered during the investigation of taxon diversity, because small-bodied taxa are  
662 underrepresented in the SZ-6 assemblage.

663

### 664 6.3.3. *Specimen shape sorting*

665

666 The shape of bones appears to be an important factor when studying bone deposition  
667 after fluvial transport, because the theoretical dispersal potential of fossils depends on the  
668 bone shape besides its size and density (Behrensmeyer, 1975). The bones became shape

669 sorted during transport because spherical and rod-like fossils are transported earlier and easier  
670 than disc- and blade-shaped bones (Frostick and Reid, 1983).

671 *Method:* At first we measured all three axes of bones of SZ-6 assemblage, which are  
672 referred to as length, width and thickness, regardless of the anatomical orientation of the  
673 measured bone (number of measured bones was 2475). Following the empirical model of  
674 Frostick and Reid (1983) we used the ratios of the measured axes ( $D2/D3$ ;  $D3/D2$  that  
675 allowed dividing our specimens into four subcategories: sphere, rod, disc and blade shapes.  
676 The microfossil assemblage was excluded from this part of the analysis because their different  
677 size and shape sorting may distort the evaluation of the studied bone assemblage (Blob and  
678 Fiorillo, 1996). Furthermore, we compared the occurrence of shape categories of bones in the  
679 SZ-6 vertebrate assemblage with the ideal relative occurrence of elements in a complete  
680 skeleton per taxon (Table 4) in order to observe which shape category is frequently  
681 underrepresented relative to its expected value (Britt et al., 2009).

682 *Results:* The disc- and blade-like elements are the most common specimens (about  
683 80%) in the SZ-6 assemblage while the comparatively mobile shape categories of bones  
684 (spherical and rod-like shape) are far less frequent (Fig. 8). However, when comparing the  
685 frequencies of isolated bones shape categories with their expected values in a complete  
686 skeleton of taxon (based on Table 4), the distribution of shape categories was random (Table  
687 5). The later approach can be regarded more realistic, because it includes a value of reference  
688 (expected value of bones per shape category) and it indicates only which shape categories are  
689 over- or underrepresented in the SZ- 6 assemblage in Iharkút locality.

690 *Comments:* There is no strong evidence for shape sorting in the SZ-6 assemblage,  
691 because the over- or underrepresentation of shape categories in the fossil material was random  
692 when compared to their occurrence in a complete skeleton. This fact suggests that the Iharkút  
693 taphocoenose was not a typical fluvially transported assemblage; rather elements were

694 transported for a short time or by high density (or energy) flows (e.g. Rogers, 2005; Britt et  
695 al., 2009). It also conceivable that there were multiple sources of bone input (e.g. Aslan and  
696 Behrensmeyer, 1996) and thus these were transported and sorted in different ways.

697

#### 698 **6.4. Discussion**

699

700 The Iharkút vertebrate assemblage is fragmented and highly dispersed, therefore the  
701 assessment of taxon diversity is complicated.

702 The use of the NISP method would be reasonable for the analysis of taxon distribution  
703 in the Iharkút vertebrate collection because the material is very fragmented, dispersed,  
704 transported and the possibility of association is zero (following Badgley, 1986b) for most taxa  
705 (excepting ankylosaur remains). However, the pattern of NISP distribution in the Iharkút  
706 assemblage is unexpected when compared with that seen in modern ecosystems which tend to  
707 have a higher abundance of fish and amphibians (or other small-bodied taxa) compared to  
708 larger-bodied reptiles or mammals (Oindo et al., 2001). The NISP index profile of the Iharkút  
709 assemblage differs from modern ecosystems from fluvial environments because the remains  
710 of terrestrial animals (e.g. dinosaurs) are more frequent than those of aquatic form (e.g.  
711 amphibians or fish) despite the fact that the depositional area was a typical alluvial, floodplain  
712 palaeoenvironment. It is important to note that there is a taphonomic bias against the small  
713 bodied animals in the SZ-6 vertebrate assemblage. Small-sized fossils are more frequently  
714 underrepresented than the larger size categories and this may contribute to the fact that  
715 amphibians, fish or small lizards show lower frequency in the NISP calculation.

716 On the contrary, the MNI profile of the Iharkút vertebrate assemblage shows a  
717 distribution similar to that seen in modern ecosystems. In this case small-bodied taxa (e.g.  
718 fish, amphibians, lizards) are relatively more frequent than large-bodied taxa (e.g. dinosaurs).

719           Furthermore there are several characters of the SZ-6 vertebrate assemblage that  
720 suggest that this site acted as a "trapping place" for the bones.

721           (1) 9099 bones and fragments (and 2271 teeth) were discovered from an  
722 approximately 400 m<sup>2</sup> area, showing densities ranging up to 23 specimens/m<sup>2</sup>. The relatively  
723 high fossil density (Fiorillo et al., 2010) in site SZ-6 of Iharkút may be interpreted as sign of a  
724 preferred bone accumulation place where the fossils could have been deposited and  
725 concentrated through the attritional processes.

726           (2) There is no strong evidence for shape sorting which would refer to transport  
727 conditions (Aslan and Behrensmeyer, 1996). The absence of shape sorting in the SZ-6  
728 remains may suggest that the distance and/or time of transportation was not too long and it  
729 raises the possibility that several elements from the same individual accumulated together in  
730 the same horizon (Behrensmeyer, 1991; Badgley, 1986a,b).

731           (3) The presence of a limited number of associated and even articulated ankylosaur  
732 skeletons in the same horizons as the isolated bones may indicate that dispersion was not  
733 always very significant during bone accumulation.

734           (4) The relatively high skeletal representation for many taxa may suggest that a large  
735 proportion of their skeletons was deposited together in a particular place and sorting was not  
736 significant before bone accumulation.

737           Due to the above listed arguments, we suggest that the place of site SZ-6 was a  
738 trapping place for bones rather than a slowly filling up depositional area, thus the calculation  
739 of taxon distribution by MNI is more realistic (Badgley, 1986a,b) in the case of the SZ-6  
740 assemblage in Iharkút locality.

741

742

743 **7. TAPHONOMIC FEATURES OF THE BONE ASSEMBLAGE OF SITE SZ-6,**  
744 **IHARKÚT LOCALITY**

745

746 Many physical, chemical or biological destructive agents conspire during the  
747 deposition of a bone assemblage which result in different damages on the bone surface; these  
748 different types of modifications are diagnostic and distinguishable from each other (based on  
749 the experimental studies) thus they play a critical role in a better understanding of the  
750 taphonomic history (Behrensmeyer, 1991; Lyman, 1994a).

751

752 **7.1. Taphonomic features of the isolated bone assemblage at site SZ-6 from Iharkút**  
753 **locality**

754

755 The majority of the Iharkút vertebrate assemblage consists of isolated bones, which  
756 suggest a different taphonomic history from that of the associated or articulated skeletal  
757 materials (Coard and Dennell, 1995) and suggest presence of dispersal processes before  
758 burial.

759

760 *7.1.1. Abrasion features on isolated bones*

761

762 The investigation of bone abrasion refers to the physical erosion of the surface of  
763 bones before the final burial (Behrensmeyer, 1991; Fernández-Jalvo and Andrews, 2003).  
764 Abrasion is an indicator of the interaction between sediment particles and bones, therefore can  
765 be used indirectly for estimating the distance bones were transported (Behrensmeyer, 1982;  
766 Aslan and Behrensmeyer, 1996; Zeigler, 2003). However, many observations in natural  
767 conditions pointed out that the abrasion of bones does not always correlate with transportation

768 (Behrensmeyer 1982, Aslan and Behrensmeyer 1996). In addition, there are other  
769 taphonomic processes or agents (e.g. trampling, chewing) that generate similar damage on the  
770 edges or external surfaces of bones (Behrensmeyer et al, 1986; Britt et al., 2009; Domínguez-  
771 Rodrigo et al., 2009).

772 *Methods:* We examined alterations related to physical grinding and polishing on the  
773 edges and/or surface of vertebrate fossils in the SZ-6 assemblage and divided the fossils into  
774 two categories (1: unabraded bone; 2: abraded bone). The bone pebbles and microvertebrates  
775 were excluded from this part of the analysis because their different “transportation history”  
776 distorts the evaluation of the identified bones assemblage (see above).

777 *Results:* 2603 isolated bones were observed to detect abrasion. About 60% of the  
778 examined isolated bones are abraded (Fig. 9A). The bones of terrestrial animals show some  
779 evidence of abrasion in greater proportion than those of aquatic or semiaquatic taxa (Fig. 9B)  
780 and smaller-sized bones are more frequently abraded than larger ones (Fig. 9C). The  
781 ankylosaurs show the highest degree of abrasion in the vertebrate material of the site SZ-6  
782 (Fig. 9D).

783 *Comments:* The relatively high percentage of abraded bones indicates that more than  
784 half of the site SZ-6 material was exposed to physical impacts before final burial. This does  
785 not imply that most fossils from Iharkút were long-term transported, because empirical  
786 experiments have shown that bones can travel many kilometres without evidence for abrasion  
787 (Behrensmeyer, 1982, 1991; Aslan and Behrensmeyer, 1996). The high density flow (which  
788 played a significant role in the bone accumulation at the SZ-6 site of Iharkút mine) probably  
789 caused significant impact on the bone surfaces when the bones came in contact with the  
790 moving sediment particles. This presumably highly energetic (but short-term) process could  
791 have grinded the edges and/or surface of the transported bones. The fact that small-sized  
792 bones are more frequently abraded than larger ones can be explained that there is evidence

793 that small bones weather more rapidly than large ones (Behrensmeyer, 1978) and weathered  
794 bones become strongly rounded after a short period of abrasion more easily than fresh bones  
795 (Fernández-Jalvo and Andrews, 2003). The fossils of terrestrial animals show higher rate of  
796 abrasion than the bones of aquatic or semiaquatic animals, which might be also related to  
797 different weathering stages of the bones before abrasion (Behrensmeyer, 1975; Fernández-  
798 Jalvo and Andrews, 2003). The ankylosaur remains are more abraded compared to the bones  
799 of other dinosaur taxa. This suggests some differences in their habitats. Ankylosaurs might  
800 have been members of the floodplain channel environment so their bones had more  
801 probability for fluvial abrasion. Effect of trampling was also detected both in the skeletal and  
802 the isolated bone material (*in situ* breakage type; Fig.10) suggesting that abrasion partly  
803 resulted from trampling (Conybeare and Haynes, 1984; Behrensmeyer et al., 1986; Britt et al.,  
804 2009).

805

#### 806 7.1.2. Weathering on isolated bones

807

808 Weathering is the result of the effects of physical and chemical agents during which  
809 the organic and inorganic components of bones got separated from each other or have been  
810 destroyed *in situ* on the surface or within the soil zone (Behrensmeyer, 1978; Lyman and Fox,  
811 1989).

812 *Methods:* We attempted to divide the fossils of site SZ-6 into two categories: 1)  
813 unweathered bones; 2) weathered bones. The bone pebbles (and microvertebrates) were  
814 excluded from this part of the analysis.

815 *Results:* Presence or absence of weathering on the bone surface could be observed  
816 only in the case of 15% of the identified isolated bones because in the other cases abrasion or  
817 pyrite crust development on the bone surfaces made this type of observation impossible.

818 About 6% of the observed material showed flaking associated with cracks due to weathering  
819 (Fig. 11A). The turtle and ankylosaur remains are more highly weathered than bones of other  
820 taxa in the site Sz-6 assemblage (Fig. 11B).

821 *Comments:* Observation of weathering on bone surfaces in the SZ-6 remain cannot be  
822 considered of full value due to the following reasons: (1) the Iharkút vertebrate assemblage is  
823 highly abraded. The flaking resulted from weathering presumably developed on the bone  
824 surface sooner than the abrasion and thus the latter process might have overwritten  
825 characteristics of weathering in many cases (Lyman and Fox, 1989). (2) In other cases pyrite  
826 crust covers the bone surface and masks the traces of modification. (3) bones of fish, reptiles  
827 and birds are different from the mammals in weathering features (Behrensmeyer, 1978) and  
828 therefore the direct comparison of Mesozoic non-mammalian fossil assemblages with the  
829 weathering stages of Behrensmeyer (1978) is questionable ( e.g. Ryan et al., 2001; Britt et al.,  
830 2009; Csiki et al., 2010). For these reasons it can be stated that evaluation of the weathering  
831 characteristics is strongly limited in the SZ-6 assemblages and therefore the utility of this  
832 method for palaeoecological interpretations is also limited

833 .

834

### 835 *7.1.3. Frequencies of breakage types in isolated bone assemblage*

836 The type of break on a fossil bone provides information whether the specimen was  
837 fresh or already “fossilized” or mineralized when it got broken. Patterns of breakage in fossil  
838 accumulations are of great importance for understanding the different agents (trampling,  
839 carnivore gnawing, fluvial transport etc.) acting during the deposition of a vertebrate  
840 assemblage (Haynes, 1983; Todd and Rapson, 1988; Ryan et al., 2001).

841 *Methods:* We distinguish oblique, longitudinal and smooth transverse fracture categories in  
842 the site SZ-6 assemblage (see Supplementary data 1) Furthermore the presence or absence of

843 epiphyses of limb bones was documented separately in this remains. The bone pebbles and  
844 microvertebrates were excluded from this part of the analysis.

845 *Results:* 88% of the site SZ-6 vertebrate assemblage is broken indicating a high  
846 fragmentation rate (Fig.12A). About 64% of the fractures have indeterminate origin; 18% of  
847 the broken bones show different types of “pre-fossilization” fracture (oblique and  
848 longitudinal) while only 3% of the fracture was created in the fossildiagenetic phase. There is  
849 no significant difference in the distribution of breakage types between the assemblages of  
850 aquatic/semiaquatic and terrestrial taxa (Fig. 12B). About 71% of the limb bones preserve the  
851 epiphysis at least one end (Fig. 12C).

852 *Comments:* There are three main groups of destructive factors which can cause  
853 significant but varying degrees of fractures in a bone assemblage. These are carnivore and/or  
854 scavenger effects, trampling, and transportation (Haynes, 1983; Fiorillo, 1991; Jennings and  
855 Hasiotis, 1996; Domínguez-Rodrigo et al., 2009; Noto et al., 2012). In Cenozoic vertebrate  
856 remains the high degree of fragmentation of the bone material can be caused by mammalian  
857 carnivores because their teeth are suited for crushing bones (Fiorillo, 1991; Spencer et al.,  
858 2003; Faith and Behrensmeyer, 2006; Faith et al., 2007). Nevertheless, such fragmentation is  
859 subordinate in dinosaurs-dominated ecosystems, because the teeth of theropods were  
860 appropriate for cutting meat (Fiorillo, 1991; Ryan et al., 2001; Farlow and Holtz, 2002;  
861 D’Amore and Blumenschine, 2012) and there is only a limited evidence that they could crush  
862 bones (Chin et al., 1998; Hone and Rauhut, 2009). The *Allodaposuchus*-like crocodiles with  
863 conical teeth might have crushed bones, when they try to place the food item in the most  
864 adequate position for swallowing (Noto et al., 2012; Botfalvai et al., 2014). However the role  
865 of crocodiles in fragmentation of SZ-6 bone assemblage could be limited because the  
866 crocodiles attempt to swallow large parts of the carcasses and thus the fragmentation is  
867 minimal when carcasses are consumed by crocodiles (Njau and Blumenschine, 2006) The

868 freshwater mosasaur *Pannoniasaurus*, a potential top predator known from the locality, has  
869 slender, pointed and slightly distally curved teeth; a tooth morphology that, in contrast to  
870 conical teeth, is considered to be inadequate for crushing bone (Botfalvai et al., 2014). Based  
871 on the foregoing list, carnivore activity did not play a (significant) role in the fragmentation of  
872 Iharkút vertebrate remains just as in other Mesozoic bone assemblages.

873 Bone fracturing by trampling is a significant and frequent agent in terrestrial bone  
874 assemblages (Haynes, 1983; Villa and Courtin, 1983; Olsen and Shipman, 1988; Gates, 2005;  
875 Britt et al., 2009; Domínguez-Rodrigo et al., 2009). The *in situ* breakage may be interpreted  
876 as resulting from trampling (Gates, 2005; Britt et al., 2009), and such fracture type occurs in a  
877 few cases in the isolated (Fig. 10) and associated material (e.g. MTM V.152.1.) of the SZ-6  
878 assemblage. Only 3% of ribs show longitudinal splintering, which type of fracture that is  
879 otherwise common in a trampled material (Haynes, 1983). The results of our investigation  
880 suggest that the presence of a trampling agent is detectable in the Iharkút material, but it may  
881 not be sufficient to explain the high fragmentation rate of isolated bones.

882 If most of the bones were transported by a high density (energy) flow (hypothesis  
883 supported by sedimentologic studies in the basal breccia at site SZ-6) then bones could suffer  
884 fragmentation on contact with the substrate or other transported materials. Some authors  
885 questioned the possibility of bone breakage during fluvial transport, because the bones  
886 become rounded and abraded rather than broken or fractured when transported in water  
887 (Behrensmeyer, 1975; Holz and Barberena, 1994). However, the action of high density flow  
888 may suggest a more significant destructive impact for the bones which could result in higher  
889 fragmentation rate in the fossil assemblage. High energy and density flow can transport large-  
890 sized tree trunks and other sediment particles which can produce significant physical impact  
891 for the transported bones when these collide with each other (Lancaster and Hayes, 2003;  
892 Britt et al., 2009). The basal breccia of site SZ-6 contains larger-sized tree trunks (e.g. an 8 m

893 long Araucariaceae trunk was discovered in close proximity <2 m of the 4<sup>th</sup> partial ankylosaur  
894 skeleton) and highly fragmented bones which were all transported together. Simultaneous  
895 presence of the two groups with high current velocity may induce fractures in the transported  
896 bone assemblage.

897         The high proportion of oblique and longitudinal fractures indicates that most bones  
898 were fresh, collagen-rich elements when broken (Haynes, 1983; Pereda Suberbiola et al.,  
899 2000). The low ratio of the fossildiagenetic fracture type may suggest that: (1) sediment  
900 reworking within the channel was limited (Behrensmeyer, 1982; Badgley, 1986b; Aslan and  
901 Behrensmeyer, 1996); (2) the site suffered no post-burial disturbance.

902

#### 903 *7.1.4. Other surface marks*

904

905         Pyrite crusts on the bone surface (Fig. 5E) are observed in min. 4% of the Iharkút  
906 macroscopic vertebrate material (this parameter was observed after the preparation of the  
907 bones).

908         There are few tooth-marked turtle plates and one *Iharkutosuchus* skull fragment in the  
909 Iharkút vertebrate material (Botfalvai et al., 2014). These tooth marks are bowl-shaped  
910 depressions and are often bisected pits which are characteristic of the crocodile gnawing  
911 (Njau and Blumenschine, 2009; Boyd et al., 2013). There is no evidence of theropod feeding  
912 traces in the vertebrate material of from the site SZ-6 (Botfalvai et al., 2014).

913

914

## 915 **7.2. Taphonomic features of the skeletal material from the Iharkút locality**

916

917           There are six associated and one articulated skeletons identified as *Hungarosaurus*  
918 *tormai* (Ősi and Makádi, 2009). These were classified in three subcategories; (1) associated  
919 incomplete skeleton which includes at least two different major segments of the skeleton  
920 (Csiki et al., 2010), (2) associated partial skeleton which includes only one segment of the  
921 skeleton (Heinrich, 1999; Csiki et al., 2010), (3) articulated partial skeleton which includes  
922 one segment of the skeleton where the skeletal elements are in contact and retained their  
923 original anatomical position (Badgley, 1986a). The more detailed description of the  
924 taphonomic features and stratigraphic position of skeletal remains from Iharkút is described in  
925 Supplementary data 3.

926

#### 927 *7.2.1. Associated incomplete skeletons*

928

929           *Material:* 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup> and 5<sup>th</sup> skeletons (MTM V.152; MTM 2007.26; MTM 2007.24;  
930 MTM 2007.25). They included different parts of the bodies (Figs. 5E and 13-14) which  
931 belong to different disarticulation sequences (based on empirical observations by Hill, 1979;  
932 Hill and Behrensmeyer, 1984; Cameron and Oxham, 2012; Cambra-Moo and Buscalioni,  
933 2003).

934           *Taphonomic interpretations:* The 1<sup>st</sup> and 3<sup>rd</sup> skeletons are limited in the number of the  
935 bones preserved which does not allow a precise reconstruction of their detailed taphonomic  
936 history (see Supplementary data 3). Furthermore the 1<sup>st</sup> skeleton was discovered in a  
937 sandstone block, found separately in an overburden dump and probably was moved from  
938 other parts of the skeleton, thus it is not known how much and what kind of other parts of  
939 skeleton were preserved in the original associated skeleton.

940           Resistant elements of the 2<sup>nd</sup> (holotype) skeleton of *Hungarosaurus*, such as the  
941 synsacrum or skull, can only be broken through significant mechanical effects; however, their

942 scattering was limited, being the bones found close to each other (Fig. 13). These two factors  
943 (significant mechanical impact and limited dispersion) suggest that trampling (and perhaps  
944 scavenging) was in large part responsible for the destruction of the 2<sup>nd</sup> ankylosaur skeleton.  
945 Trampling is indeed often the main destruction agent in the soft substrate of abandoned  
946 channel environments (Behrensmeyer, 1988; Capaldo and Peters, 1995). The enclosing  
947 sediment (siltstone with plant fragments which were deposited on the coarse grained  
948 sandstone) indicates reduced current velocities which made the stranding of the corpse  
949 possible. The carcasses have been subsequently exposed to biological and mechanical agents  
950 (e.g. decay, trampling, scavenging) during the disarticulation. The skeletal material contains  
951 both the earliest disarticulating (cervical vertebrae, ribs, osteoderms) and most resistant  
952 elements (limbs and lumbar vertebrae) (Cambra-Moo and Buscalioni, 2003) together within a  
953 48 m<sup>2</sup> area, which may indicate that disarticulation of the skeleton began after the final  
954 deposition of the corpse. There is no evidence for (longer term) transportation of the skeletal  
955 elements from a primary accumulation place to the final one. The elements of the 2<sup>nd</sup> skeleton  
956 of *Hungarosaurus* have been dispersed by weak currents after accumulation and  
957 disarticulation, which currents could spread the bones over a restricted area (Fig. 13).

958         The enclosing sediment (coarse sandstone), composition (several parts of the body are  
959 represented in the material; Fig. 14C) and taphonomic features of the 5<sup>th</sup> ankylosaur skeleton  
960 (see Supplementary data 3) indicate that the corpse floated with the currents to the site when  
961 soft tissue and ligaments still kept parts of the body together. When the transportation of the  
962 carcass stopped and skeletal degradation was started by biological agents (decay, scavenging),  
963 the currents were occasionally still sufficient to move parts of the body and thus progressively  
964 dissociated the skeletal elements to arrange them in a disarticulated but associated position.  
965 Skull elements were not found in the 5<sup>th</sup> ankylosaur skeleton material, but the mandibles

966 remained with the deposited elements which is not an uncommon phenomenon (Tooth, 1965;  
967 Dodson, 1971; Weigelt, 1989:85; Holz and Barberena, 1994; Capaldo and Peters, 1995).

### 968 7.2.2. *Associated partial skeletons*

969

970 *Material:* 4<sup>th</sup> and 7<sup>th</sup> *Hungarosaurus* skeletons (MTM 2007.23, MTM PAL.2013.57.1)  
971 including the elements of the hip region in associated position (Fig. 14B).

972 *Comments:* Elements of the hip region (pelvic girdle and synsacrum) of ankylosaurs  
973 are much more resistant to physical effects (e.g. transportation) than other skeletal parts,  
974 because these are usually co-ossified, hence they are often preserved in articulated or  
975 associated position (e.g. Pereda Suberbiola et al., 2000), despite of the high energy  
976 transportation.

977 The pelvic girdle elements were in an articulated position when they got deposited on  
978 the bottom of the channel. This assumption is based on the model of random scattering  
979 described by Hill (1979) saying that the probability of dispersion of disarticulated bones of  
980 individual “A” is always higher than the probability of disarticulated bones of individual “A”  
981 concentrated together in the same space. Presumably, the elements of the deposited pelvic  
982 girdle suffered damage from biological agents, because several skeletal elements were broken  
983 in the biostratonomic phase (oblique fracture type).

984

### 985 7.2.3. *Articulated partial skeleton*

986 *Material:* 6<sup>th</sup> skeleton (MTM PAL.2013.58.1) composed of the complete hip region  
987 including pelvic elements and the sacral region, but not the sacral armour elements (Fig. 5F).

988 *Comments:* The original skeleton presumably began to become decomposed by  
989 biological and physical effects and the parts of the skeleton were separated from each other.  
990 The hip region is a resistant part of the body and its density and size might have been greater

991 than the other segments of the skeleton, consequently it was transported to a different place  
992 from the other bones. Furthermore, the hip region might have remained articulated far longer  
993 than the other parts of the body because its elements were ossified. It is plausible, that these  
994 parts of the ankylosaur skeleton might have been dispersed with different rate than the other  
995 parts by water action (Nasti, 2005), because the hydraulic transport potential of articulated  
996 remains is often greater than that of the disarticulated bones (Coard and Dennell, 1995). This  
997 assumption may explain the frequency of the pelvic and sacral regions among the associated  
998 material of the SZ-6 assemblage.

999

1000

### 1001 **7.3. Discussion and interpretation of taphonomic features of Iharkút bones material**

1002

1003 On the basis of taphonomic investigations performed on the vertebrate material of site  
1004 SZ-6 it is suggested that the assemblage consists of three different taphonomic fractions.

1005 The first fraction includes unidentifiable bone pebbles which were transported for a  
1006 long time with the bed-load sediment of ancient streams from the background area. The high  
1007 rate of abrasion and the spherical shape of these elements indicate that they were reworked  
1008 many times and exposed to channel bottom processes for a long time, during which they  
1009 suffered significant physical impact and destruction before the final burial (Behrensmeyer,  
1010 1988; Wood et al., 1988).

1011 The second group includes about 88% of the Iharkút collection, containing most of the  
1012 identified isolated bones and teeth. Most of these isolated bones were abraded and fractured  
1013 (Figs. 9 and 12). The isolated bones were exposed to physical and/or biological destruction in  
1014 the preburial phase. Trample-induced breakage (*in situ* breakage type; Fig. 10) is detectable in  
1015 the isolated bone material, however, fractures observed in the bones were also formed during

1016 transportation by high density flows, since there is evidence for large-sized tree trunks  
1017 transported alongside the bones; occasional collision between these trunks and the transported  
1018 bones could have also resulted in bone fractures in the Iharkút material. Skeletal  
1019 representation (bones of different size, density and shape were deposited in the same horizon),  
1020 abrasion stages and fragmentation ratio vary among terrestrial and aquatic/semiaquatic taxa  
1021 which may imply that this fraction of the Iharkút collection represents polytypic attritional  
1022 remains of isolated and dispersed elements which were deposited by fluvial processes  
1023 (Kidwell et al., 1986; Holz and Barberena, 1994; Kahlke and Gaudzinski, 2005). The high  
1024 skeletal completeness of nodosaurids ankylosaurs suggests that they were members of the  
1025 floodplain channel environment and their bones have more probability for concentration by  
1026 fluvial action (Table 4).

1027         The third fraction includes the associated and articulated bone assemblages, which  
1028 have a different taphonomic history from that of the isolated bones. All the  
1029 associated/articulated skeletons are from ankylosaurs and this fact further supports that  
1030 ankylosaurs lived close to the place of final bone accumulation. The associated skeletal  
1031 material shows high fragmentation rate (see Supplementary data 3). The greater proportion of  
1032 fractures was created by a trampling agent (*in situ* breakage) after the deposition. The  
1033 extremely high frequency of ankylosaur hip regions preserved in the Iharkút locality suggests  
1034 that this represented the most resistant part of the body. The pelvic girdle elements of  
1035 ankylosaurs were originally co-ossified, hence they could have remained far longer in  
1036 articulated position compared to the other parts of the body.

1037         The low completeness values of the skeletons in the Iharkút collection may indicate  
1038 that the carcasses were exposed to subaerial or subaqueous destructive processes and then  
1039 they were transported by fluvial action during which parts of the skeleton were dispersed  
1040 before final burial (Holtz and Barberena, 1994; Davis and Briggs, 1998; Brand et al., 2003;

1041 Cameron and Oxenham, 2012; Syme and Salisbury, 2014). Decay processes affecting the  
1042 carcasses preceded scattering of the skeleton (which was generated by fluvial action during  
1043 short term transportation), because currents can only disarticulate the corpse after the most  
1044 digestible tissues have been removed (Tooth, 1965; Syme and Salisbury, 2014). Furthermore,  
1045 scavengers might have been also significant agent in disarticulation or degradation of the  
1046 studied skeletons, because empirical studies have documented that vertebrate (e.g. crocodiles)  
1047 and invertebrate (e.g. gastropods, insect larvae) scavengers have primary role in the  
1048 degradation of carcasses (Weigelt, 1989:13; Hill and Behrensmeyer, 1984; Oliver and  
1049 Graham, 1994; Davis and Briggs, 1998; Brand et al., 2003; Carter et al., 2007; Cameron and  
1050 Oxenham, 2012; Syme and Salisbury, 2014). Real estimation of decay and disarticulation  
1051 period is not possible in the case of dinosaur remains because these processes largely depend  
1052 on the nature of skin, body size and environmental conditions (Brand et al., 2003), factors  
1053 which are poorly known.

1054         The most conspicuous feature of the skeletal materials from Iharkút is that these are  
1055 confined to only one taxon (*Hungarosaurus*) thus representing a monospecific assemblage.  
1056 This fact has a number of possible explanations:

1057         (1) The skeletal structure of ankylosaurs was favourable for articulated preservation  
1058 (e.g. because many elements were co-ossified) thus their elements could remain in a strongly  
1059 associated position far longer during transportation or exposure to subaerial destructions than  
1060 the skeletal parts of other taxa. However, this possibility can be probably discarded in the case  
1061 of the *Hungarosaurus* skeletal material from Iharkút, because in the sites of the Dinosaur Park  
1062 Formation (Upper Cretaceous, Dinosaur Provincial Park, Alberta, Canada) the number of  
1063 articulated ankylosaur skeletons is subordinate when compared to that of hadrosaurs and  
1064 ceratopsians (Wood et al., 1988). This comparison is probably relevant, because in many  
1065 cases the taphonomic characters documented in the Dinosaur Park Formation are very similar

1066 to those from the Iharkút sites if one considers the deposition or transportation of the  
1067 carcasses. At first the carcasses floated downstream as bloated carcasses in the Dinosaur Park  
1068 Formation, as it was also suggested in some Iharkút skeletons (2<sup>nd</sup> and 5<sup>th</sup> skeletons). Second,  
1069 incomplete preservation of skeletons also occurs in the Dinosaur Park Formation (as a result  
1070 of longer periods of exposure; Wood et al., 1988), as it was demonstrated in case of  
1071 ankylosaurian skeletal material from Iharkút. Third, the two most common dinosaur groups of  
1072 the Dinosaur Park Formation, the ornithopods (hadrosaurs) and ceratopsians, are also known  
1073 from the Iharkút sites (Ősi et al., 2010b, 2012b) but their fossils are very rare and their  
1074 skeletons have not yet been discovered. Furthermore, Dodson (1971) also mentioned that in  
1075 the Dinosaur Park Formation the number of ankylosaur skeletons is also significantly less  
1076 common than those of ornithopods and ceratopsians, which confirms that the skeletal  
1077 structure of ankylosaurs was not more favourable for articulated preservation than that of  
1078 other dinosaur taxa (ornithopods, ceratopsians and theropods) from the Iharkút locality.

1079 (2) Ankylosaurs lived in a habitat close to the site of deposition, consequently the  
1080 probability of articulated preservation was higher than for other taxa, because their bones  
1081 were transported for a shorter period. This habitat preference (which was demonstrated by the  
1082 measure of relative skeletal completeness in the isolated bone assemblage by Shotwell  
1083 (1955)) definitely played a significant role in the associated and articulated preservations of  
1084 ankylosaur bone material in the Iharkút sites. However, it is unlikely that only the ankylosaurs  
1085 were members of a proximal community and all the other taxa lived in more distal habitat(s).  
1086 For instance, *Iharkutosuchus* remains include numerous unabraded skulls with in situ teeth  
1087 (Ősi, 2008a) which may indicate that the *Iharkutosuchus* material was not transported from  
1088 distant areas, but instead these animals died close to the site of final deposition (e.g.  
1089 Behrensmeyer, 1982, 1988; Aslan and Behrensmeyer, 1996). The skull of *Iharkutosuchus* is  
1090 flattened and rather disc-like, a morphology which could have lowered transport rates (based

1091 on empirical observations) compared to spherical or rod-like fossils (Frostick and Reid,  
1092 1983). The presence of numerous disc-shaped and heavier (high density) bones in the  
1093 *Iharkutosuchus* material probably indicates that this crocodile was also member of the  
1094 proximal habitat community as it was concluded in ankylosaurs; nonetheless, skeletons of  
1095 *Iharkutosuchus* are yet to be discovered. Although the suggested habitat of ankylosaurs, close  
1096 to the place of deposition might have played a significant role in the relatively common  
1097 articulated and associated preservation of their bones in the Iharkút sites; this is, however, not  
1098 considered to be a sufficient explanation for the occurrence of a monospecific assemblage of  
1099 associated/articulated ankylosaur skeletons in the Iharkút locality.

1100 (3) The monospecific skeletal material of Iharkút may represent a mass death  
1101 assemblage (see e.g. Wood et al., 1988; Sander, 1992; Varricchio and Horner, 1992; Henrici  
1102 and Fiorillo, 1993; Coria, 1994; Holz and Barberena, 1994; Schwartz and Gillette, 1994; Ryan  
1103 et al., 2001; Lucas et al., 2010; Mukherjee and Ray, 2012). A mass death assemblage  
1104 includes remains of animals (possibly member of a herd or group of animals) that died over a  
1105 brief time span due to a single agent of death (Haynes, 1988). It is often very complicated to  
1106 distinguish mass mortality from mass accumulation in terrestrial and/or fluvial environments,  
1107 because many agents can create individual rich mass accumulation of fossils by reworking,  
1108 transporting and concentrating attritional assemblages (e.g. scavenger and carnivore effect or  
1109 fluvial transportation), and these occurrences are easily confused with mass mortality  
1110 assemblages (Turnbull and Martill, 1988; Haynes, 1988; Capaldo and Peters, 1995, Lucas et  
1111 al., 2010). Mass mortality events can be caused by natural events such as drought (Shipman,  
1112 1975; Conybeare and Haynes, 1984; Rogers, 1990; Varricchio and Horner, 1992; Schwartz  
1113 and Gillette, 1994; Fiorillo et al., 2000; Gates, 2005; Mukherjee and Ray, 2012), high density  
1114 debris flows (Turnbull and Martill, 1988,; Rogers 2005), volcanic or gas eruptions (Rogers et  
1115 al., 2001; Baele et al., 2012), poisoning or infections (Varricchio and Horner, 1992;

1116 Varricchio, 1995; Henrici and Fiorillo, 1993), trapping (Eberth et al., 2010; Domingo et al.,  
1117 2013), miring in soft ground (Sander, 1992; Spencer et al., 2003; Varricchio et al., 2008;  
1118 Eberth et al., 2010) and drowning during the high-flood events (Wood et al., 1988; Fiorillo,  
1119 1991, Capaldo and Peters 1995, Ryan et al. 2001, Kahlke and Gaudzinski 2005, Gangloff and  
1120 Fiorillo 2010).

1121         The taxonomic exclusiveness and relatively high frequency of the ankylosaur  
1122 skeletons preserved in a localized area (about 400 m<sup>2</sup>), as well as their similar taphonomic  
1123 features raise the possibility that several individuals of one species were killed in one place  
1124 and over a brief time span. The hypothesis of mass mortality of the Iharkút ankylosaurs is  
1125 supported by the following observations: six associated and one articulated *Hungarosaurus*  
1126 skeletons were discovered from an area of approximately 400 m<sup>2</sup> and in many cases the  
1127 skeletons were found close to each other in the same layer (e.g. 2<sup>nd</sup>-3<sup>rd</sup> and 6<sup>th</sup>-7<sup>th</sup> ankylosaur  
1128 skeletons, respectively). The associated skeletal material from Iharkút has almost uniform  
1129 taphonomic features (e.g. limited abrasion, absence of weathering, often complete epiphyses)  
1130 which may also suggest mass mortality. The enclosing layer shows sign of rapid deposition  
1131 (clay clasts and sand with plant fragments, poorly sorted sediment), which is a sedimentologic  
1132 criterion of a mass-death assemblage (Turnbull and Martill, 1988).

1133         The question of whether the *Hungarosaurus* mass assemblage is a result of  
1134 catastrophic (nonselective) or noncatastrophic (selective) mass mortality (Conybeare and  
1135 Haynes, 1984, Turnbull and Martill, 1988; Varricchio and Horner, 1992; Henrici and Fiorillo,  
1136 1993; Lyman, 1994a:118; Heinrich, 1999; Ryan et al., 2001; Kahlke and Gaudzinski, 2005;  
1137 Baele et al., 2012; Mukherjee and Ray, 2012) is difficult to answer, because the number of  
1138 specimens (only seven carcasses) is limited for estimating a U-shaped or L-shaped age profile  
1139 of the Iharkút skeletal material. The skeletal material from Iharkút is most probably composed  
1140 of both adult and subadult individuals, but this hypothesis is supported only partly by accurate

1141 bone histological examinations (Company and Ósi, 2012). Several studies documented that  
1142 rich bone accumulation of dinosaurs (e.g. ceratopsids) could have been the results of mass  
1143 death events of herds that occurred when the herd attempted to cross the flooded river (Wood  
1144 et al., 1988; Fiorillo, 1991; Ryan et al., 2001; Gangloff and Fiorillo, 2010). We suggest that  
1145 the cause of death of the Iharkút ankylosaurs was also probably drowning when the herd  
1146 attempted to cross the flooded river, as supported by the following arguments: drowning is a  
1147 frequent cause of death in terrestrial animals with herding lifestyle (Weigelt, 1989; Capaldo  
1148 and Peters, 1995; Ryan et al., 2001; Rogers and Kidwell, 2007; Gangloff and Fiorillo, 2010),  
1149 documented in the fossil record by several authors (Turnbull and Martill, 1988; Wood et al.,  
1150 1988; Fiorillo, 1991; Kahlke and Gaudzinski, 2005). Sediments of periodic heavy flooding  
1151 events were detected in Iharkút locality since the basal breccia of the site SZ-6 (which  
1152 contains most of the ankylosaur skeletons) was deposited during a high density flow (see  
1153 above, the sedimentologic settings). As it was pointed out based on trackways, ankylosaurs  
1154 preferred herding lifestyle (McCrea et al., 2001) and the structure of their body (large and  
1155 heavy osteoderms on the body) might have been unfavourable for swimming across the  
1156 flooded river.

1157         There are no evidences for other possible causes of death, but this does not mean that  
1158 other causes can be excluded conclusively. Drought as another common cause of mass-death  
1159 events could not have been detected at the locality because there are no sedimentologic  
1160 evidences for periodic drought (such as mud cracks or evaporites etc.) and the flora suggests a  
1161 subtropical, moist climate (Bodor et al., 2012). Furthermore, the faunal composition and  
1162 taphonomic observations (most of the skeletons are preserved in disarticulated position, small  
1163 number of juvenile individuals) clearly against this hypothesis (Shipman, 1975; Rogers, 1990;  
1164 Varricchio and Horner, 1992; Schwartz and Gillette, 1994; Gates, 2005). There are not  
1165 taphonomic evidences for miring in the soft ground such as articulated preservation, strongly

1166 recovered neck, *in situ* death and skeleton pose (Sander, 1992; Eberth et al., 2010). Disease or  
1167 poisoning, as possible causes of mass-death events, are theoretically possible (Varricchio,  
1168 1995; Henrici and Fiorillo, 1993; Baele et al., 2012), but detection of these agents is difficult,  
1169 and there is no evidence that modern diseases (e.g. botulism) were already present in the  
1170 Cretaceous (Henrici and Fiorillo, 1993; Gates, 2005). Furthermore, this hypothesis may not  
1171 explain the monospecific features of the skeletal assemblages. Forest fire is often associated  
1172 with catastrophic death events (Sander, 1987; Zeigler, 2003) but fire not necessarily threatens  
1173 the life of large-bodied animals significantly, because most of them can easily escape from the  
1174 endangered area (Lawrence, 1966; Singer et al., 1989). Fire-related mass death further seems  
1175 improbable, because fusinite and fossil charcoal are only sparsely present in the sediments;  
1176 only the remains of seeds and fruits were coalified, while fusinite was not detected in these  
1177 plant fossils (Bodor and Baranyi, 2012). The existence of monospecific skeletal material in a  
1178 layer deposited under high energy conditions raises the possibility that all or some of these  
1179 ankylosaurs were killed by an instantaneous event when they attempted to cross the flooded  
1180 river. The carcasses of the drowned animals drifted downstream by flotation until the current  
1181 velocity decreased and/or water column become too shallow. The deposited carcasses were  
1182 exposed to destructive processes (decay, trampling, scavenging) during which the bodies  
1183 disarticulated and certain parts of the skeletons were destroyed or scattered. The mass  
1184 deposited carcasses represent an important food source for the scavengers which can cause a  
1185 notable reduction of the skeletons (Capaldo and Peters, 1995; Spencer et al., 2003; Carter et  
1186 al., 2007). Furthermore, an empirical examination showed that commonly about 70-80% of  
1187 the bone material of mass vertebrate assemblages becomes destroyed within 1-2 years by  
1188 physical and biological destructive processes (Capaldo and Peters, 1995). Thus the low  
1189 percentages of skeletal completeness documented in the ankylosaur skeletal material from  
1190 Iharkút are not considered an unusual phenomenon.

1191           On the other hand, it cannot be excluded that these *Hungarosaurus* individuals died in  
1192 unknown death event(s) or through normal, attritional mortality in the background area and  
1193 their corpses were afterwards collected during the (ephemeral) flood events and deposited into  
1194 the studied area. We do not have unequivocal evidence for the cause of death but we have  
1195 presented a possible scenario for the death and accumulation of seven *Hungarosaurus*  
1196 individuals providing a monospecific assemblage of skeletons in the SZ-6 site of the Iharkút  
1197 locality.

1198

## 1199 **8. PALAEOECOLOGICAL CONSIDERATIONS**

1200

1201           The vertebrate assemblage of Iharkút originated from multiple bone sources, because  
1202 attritional (isolated bones) and most probably mass killed assemblages (associated and  
1203 articulated skeletal materials) are found together in the same layer, and these do not show  
1204 significant evidence for sorting by size and/or shape. This kind of vertebrate assemblages  
1205 from over extended periods (Behrensmeyer, 1982; Aslan and Behrensmeyer, 1996) are  
1206 probably represent the result of long-term time average. Thus we estimated the duration of  
1207 time averaging represented in the SZ-6 assemblage, because without it accurate  
1208 palaeoecological investigations cannot be achieved (Behrensmeyer, 1982; Kidwell and Flessa,  
1209 1996; Martin, 1999:220).

1210           The length of time represented by fluvial bone assemblages can be related to  
1211 influences of rates of sedimentation and sediment reworking as well as the preservation of  
1212 bones in floodplain sediments and soils (Aslan and Behrensmeyer, 1996). The rate of  
1213 sedimentation at site SZ-6 was probably rapid, because the channel fill formed during  
1214 ephemeral flood events as a result of high density (flash) flows. The presence of frequent  
1215 sandstone ribbon and poorly developed paleosols in the Iharkút locality probably also

1216 indicates relatively rapid sediment accumulation (Aslan and Behrensmeyer, 1996; Martin  
1217 1999:221). Sediment reworking appears to be restricted; absence of point bar accretion and  
1218 the rarity of cross-bedding in the channel fills indicate that lateral accretion of the channels  
1219 was limited in the Iharkút locality. These conditions were not favourable for the preservation  
1220 of bones in the floodplain sediments of Iharkút because “rapid sediment accumulation  
1221 inhibits paleosol development and favours low density of bones in the floodplain deposit”  
1222 (Aslan and Behrensmeyer, 1996:419). The Iharkút locality is thus generally characterized by  
1223 conditions of rapid sedimentation and limited sediment reworking as well as predominant  
1224 presence of poorly developed, hydromorphic paleosols. These conditions minimize the  
1225 duration of time averaging (based on empirical observations, amounting time intervals of  
1226 about  $10^1$ – $10^2$  years) represented in the channel-related bone assemblages (based on Aslan  
1227 and Behrensmeyer, 1996). The sedimentologic and taphonomic investigations suggest that the  
1228 vertebrate sample of site SZ-6 represents an assemblage of animals that lived approximately  
1229 at the same time in and around the ancient fluvial system and thus the palaeoecological  
1230 interpretation of the Iharkút fauna can be regarded as well supported based on the available  
1231 fossil material. Nevertheless, we have to keep in mind that the fossils from Iharkút reflect  
1232 only a fraction of the total diversity present in this area during the Santonian, a circumstance  
1233 that is true for every fossil site (Behrensmeyer, 1991; Behrensmeyer et al., 2000; Pereda  
1234 Suberbiola et al., 2000; Lyman, 2008:23).

1235         The Iharkút vertebrate assemblage is composed of aquatic, semi-aquatic and terrestrial  
1236 vertebrates. Macrofossils are dominated by bones of aquatic and semi-aquatic animals while  
1237 bones of terrestrial animals are subordinate. The estimated body size of the taxa represented  
1238 ranges from less than 1 kg (amphibians and fish) up to 650 kg (*Hungarosaurus tormai*; based  
1239 on Ősi and Makádi, 2009), while dinosaurs with larger body size (e.g. sauropods) appear to be  
1240 absent in the Iharkút vertebrate fauna. The taphonomic examinations show that both the

1241 parautochthonous and allochthonous faunal elements are present together in the fossil  
1242 assemblage; the definition of parautochthonous and allochthonous faunal elements follows  
1243 Kidwell et al. (1986).

1244 Besides gars (lepisosteiforms), the freshwater fish fauna from Iharkút is unique in  
1245 having two different pycnodontiforms, a group of fish with massively built crushing dentition  
1246 in their jaw apparatus, and were previously reported mainly from marine environments  
1247 (Kocsis et al. 2009). The fish material is probably a parautochthonous element of the SZ-6  
1248 assemblage because several well preserved mandibular with *in situ* teeth were discovered (Ősi  
1249 et al., 2012b) and the fish remains destroyed easily during the long term transportation (Smith  
1250 et al., 1988). The relatively small number of amphibian bones in the Iharkút material  
1251 represents a relatively diverse group including both allocaudatans and anurans. The anuran  
1252 fauna is mainly dominated by *Hungarobatrachus* characterized by both good swimming and  
1253 jumping abilities in the freshwater habitat (Venczel and Szentesi, 2012).

1254 The aquatic bothremydids are the most common turtle taxa in the Iharkút locality (the  
1255 material includes skulls, jaws, limb bones and numerous plates), while the freshwater  
1256 dortokids and the terrestrial *Kallokibotia* are quite rare in the fauna, and their fossils are  
1257 limited only to plate elements. Bothremydid turtles were thus probably present in large  
1258 numbers in the fluvial system close to the site of deposition, while the other turtle taxa might  
1259 belong to a more distal habitat. The four different crocodiles provide a very rich fossil  
1260 material representing about 14% of the total Iharkút vertebrate material. *Iharkutosuchus*  
1261 *makadii* was probably a member of a community living in proximity to the site of deposition  
1262 because its remains include several unabraded (disc-like) skulls with teeth (Ősi 2008a) which  
1263 may indicate that the material of *Iharkutosuchus* was not transported from distant areas. The  
1264 other, terrestrial (*Doratodon* and a *Theriosuchus*-like form) and semi-aquatic  
1265 (*Allodaposuchus*-related taxon) crocodiles cannot be examined from this point of view,

1266 because taxonomical examinations of their postcranial elements is yet not completed (Rabi,  
1267 pers. comm.).

1268         The freshwater mosasaur *Pannoniasaurus inexpectatus* is probably a  
1269 parautochthonous element of the SZ-6 assemblage because diverse remains of several  
1270 individuals (skull and mandibular elements, teeth, vertebrae, ribs, pectoral and pelvic girdle  
1271 elements of different ontogenetic stages) were discovered in the same layer and most of the  
1272 bones are well preserved (unabraded, unweathered and complete). These mosasaurs were the  
1273 largest known aquatic predators in this palaeoenvironment (Makádi et al., 2012). Besides  
1274 mosasaurs, the squamates are also represented by seven small- to medium-sized taxa of  
1275 lizards, most probably all terrestrial animals. The terrestrial macrofauna is dominated by  
1276 herbivorous dinosaurs such as ankylosaurs, ornithopods and ceratopsians, the ankylosaurs  
1277 being considered by far the dominant element of the Iharkút material (their fossils amount to  
1278 83% of the total dinosaur assemblage). The carnivorous dinosaurs are represented by three  
1279 different taxa, but their frequency is subordinate compared to herbivores. The proportion of  
1280 herbivorous and carnivorous dinosaurs is about 6:1 based on MNI calculations, while 90% of  
1281 the isolated dinosaur bone assemblage belongs to the herbivores (Table 3). The presence of  
1282 the associated and articulated skeletal remains of *Hungarosaurus* indicates that this  
1283 ankylosaur is a parautochthonous element of the local community. Furthermore, the relatively  
1284 high percentage of the skeletal completeness of isolated bones of *Hungarosaurus* also  
1285 indicates that ankylosaurs lived in a community closer to the site of deposition. The  
1286 taphonomic analysis of the ankylosaur material from Iharkút further strengthens the  
1287 previously proposed hypothesis (Horner, 1979; Lee, 1996; McCrea et al., 2001) that  
1288 ankylosaurs preferred wetland habitats such as fluvial systems and coastal regions. The other  
1289 two taxa of herbivorous dinosaurs (ornithopods and ceratopsians) are significantly less  
1290 common than the ankylosaurs as they constitute only 6% of the known dinosaur fauna. They

1291 were probably members of a community living in the distal, drier habitats, also characterized  
1292 by different vegetation (Bodor, pers. comm.). The remains of three different theropods (a  
1293 large-bodied basal tetanuran, a small-bodied abelisaurid and the small-bodied paravian,  
1294 *Pneumatoraptor fodori*, including several teeth and bones, suggest that they were  
1295 parautochthonous rather than allochthonous faunal elements. A few lightly built limb bones,  
1296 most probably referable to non-avian theropods, have been quickly destroyed or became  
1297 unrecognizable during sediment reworking or long term transportation (White et al., 1998;  
1298 Eberth et al., 2010), thus the well-preserved bone material of theropods may indicate their  
1299 parautochthonous status in the SZ-6 assemblage. Furthermore, the calculation of the skeletal  
1300 completeness of isolated theropod bones ranks these in the second position after the  
1301 *Hungarosaurus* material, which also indicates their proximal habitat.

1302 Two types of enantiornithine birds were identified on the basis of a few complete and  
1303 several fragmentary limb bones (Ósi, 2008b; Dyke and Ósi, 2010; Ósi and Buffetaut, 2011),  
1304 but their lifestyles have not been determined yet.

1305 The unusually large number of pterosaur mandibular symphyses along with various  
1306 postcranial elements indicates at least 58 individuals (Table 3). These pterosaurs probably  
1307 were members of the proximal habitat community and preferred wetland environments,  
1308 because we also found a relatively large number of fragmentary pterosaur bones (e.g. Ósi et  
1309 al., 2005) which (like the similarly thin-walled theropods bones) can be easily destroyed  
1310 during sediment reworking or long term transportation.

1311

## 1312 **9. CONCLUSIONS**

1313

1314 The sedimentologic investigations of the Santonian Csehbánya Formation at Iharkút  
1315 pointed out that the depositional environment was probably represented by the floodplain of a

1316 very low-gradient river system, based on the predominance of fine overbank deposits,  
1317 abundance of hydromorphic paleosols as well as the presence of shallow channel deposits and  
1318 fine sandstone sheets. The multiple storied, vertically aggraded shallow sandstone ribbons  
1319 with low width/depth ratios, and their relatively homogeneous texture suggest that the  
1320 channels were created by low sinuosity rivers which can be interpreted as an anastomosing  
1321 river system. The bonebed of site SZ-6, being the most important fossiliferous layer in the  
1322 Iharkút locality, indicates alternating energy conditions during bone accumulation which  
1323 resulted in fossils of different states of preservation being deposited into the same layer. The  
1324 deposits of site SZ-6 are interpreted as those of an abandoned channel which was formed  
1325 during (ephemeral) flood events. The vertebrate material from site SZ-6 represents a channel-  
1326 fill assemblage based on the following sedimentary and taphonomic attributes: (1) the site  
1327 represents a channel with mixed fill (sand-clay clast deposits alternated with fine-grained  
1328 siltstone-clay sediments) which indicates gradual abandonment during bone deposition; (2)  
1329 there is no strong evidence for shape or size sorting; (3) the rich micro- and macrofossil  
1330 assemblages from the same layer represent a wide range of body sizes in the Iharkút fauna;  
1331 (4) the preservation stage of fossils varies within same layers (ranging from highly abraded  
1332 “bone pebbles” to unabraded skulls with teeth); (5) associated incomplete and partial skeletal  
1333 material and very fragile bones (e.g. complete mandible of *Bakonydraco galaczi*) were found  
1334 in the basal section of the SZ-6 site, and these preservation modes contradict the scenario of  
1335 accumulation during sustained active flow. Based on the listed features we consider that the  
1336 assemblage of site SZ-6 was deposited when the extensive and sustained active flow already  
1337 abandoned the channel, that resulting in a sudden deposition and accumulation of the  
1338 transported bones and skeletal parts due to the reduction of current velocity. The bones are  
1339 significantly concentrated into the basal breccia layer of site SZ-6 which implies that they  
1340 were accumulated during the initial filling stages of the channel (based on Behrensmeyer

1341 1988), but the presence of associated skeletal remains in the same layer indicates that the  
1342 current velocity suddenly decreased after the cutting stages of the channel development.

1343         The isolated bone assemblage from site SZ-6 was deposited through attritional  
1344 processes within the abandoned channel: the bone pebbles were transported for a long time  
1345 with the bed-load sediments of the ancient streams from the background area while other  
1346 isolated bones (e.g. unabraded skulls of *Iharkutosuchus* with *in situ* teeth, bones of pterosaurs  
1347 and birds) were probably only transported for a short time or by sporadic flows during  
1348 rainfall. We further consider that the monospecific skeleton assemblage of the SZ-6 site  
1349 probably represents the end product of a mass-death event of herding ankylosaurs because: (1)  
1350 six associated and one articulated *Hungarosaurus* skeletons were discovered from an area of  
1351 approximately 400 m<sup>2</sup> and in many instances the skeletons were found close to each other in  
1352 the same layer; (2) they show similar taphonomic features; (3) the bone-bearing layer suggests  
1353 rapid deposition, which is a sedimentologic criterion of a mass-killed assemblage. The  
1354 existence of this monospecific *Hungarosaurus* skeletal material in a layer deposited under  
1355 high energy conditions raises the possibility that they were killed instantaneously, possibly  
1356 when they attempted to cross the flooding river. The carcasses of the drowned animals drifted  
1357 downstream by flotation until the current velocity decreased and they accumulated. The  
1358 deposited carcasses were exposed to destructive processes (decay, trampling, scavenging)  
1359 during which the bodies were disarticulated and certain parts of the skeletons were destroyed  
1360 or transported to different places.

1361

## 1362 **Acknowledgments**

1363

1364         We thank the two anonymous reviewers for their useful suggestions and the 2000–  
1365 2012 field crews for their assistance in the fieldwork. We are especially grateful to the

1366 Bakony Bauxite Mines and to Geovolán Zrt. for their logistic help. We are grateful to Ágnes  
1367 Görög (Eötvös University, Budapest), László Makádi (Hungarian Natural History Museum,  
1368 Budapest), Edina Prondvai (Eötvös University, Budapest), Ádám T. Kocsis (Eötvös  
1369 University, Budapest) and Orsolya Sztanó (Eötvös University), Budapest for helpful  
1370 discussions. Special thank goes to László Makádi for careful reading of the manuscript. We  
1371 thank Péter Gulyás, Zsófia Hajdu, Dóra Csengődi, Réka Kalmár (MTA–ELTE Dinosaur  
1372 Research Group, Budapest) for their technical assistance. The fieldwork was supported by the  
1373 Hungarian Natural History Museum, the National Geographic Society (Grant No. 7228–02,  
1374 7508–03), the Hungarian Scientific Research Fund (OTKA T–38045, PD 73021, NF 84193),  
1375 and the Hungarian Oil and Gas Company (MOL). This project was also supported by MTA–  
1376 ELTE Lendület Programme (Grant no. 95102), the Jurassic Foundation, the Hantken Miksa  
1377 Foundation, the Bolyai Fellowship (A.Ő). We thank the staff of the Department of Applied  
1378 and Physical Geology and the Department of Palaeontology, Budapest, for their support and  
1379 help provided through the years.

2088 **Figure 4.** Schematic stratigraphic section of the sites SZ-7-8 showing the main  
2089 palaeoenvironments and lithofacies associations.

2090

2091 **Figure 5.** Bonebed of site SZ-6 and aspect of different preservation of Iharkút vertebrate  
2092 assemblage. A. bone pebbles. B. Well preserved isolated *Pannoniasaurus* vertebra. C. Well  
2093 preserved skull of the *Iharkutosuchus makadii* (“complex” skeletal element). D. Well  
2094 preserved pterosaur mandible in the enclosing sediment at site SZ-6 (left) and after the  
2095 preparation (right). E. Associated incomplete *Hungarosaurus* skeleton (MTM V.152). F.  
2096 Articulated *Hungarosaurus* partial skeleton (MTM PAL.2013.58.1). G. Turtle plate fragments  
2097 with pyrite crust.

2098

2099 **Figure 6.** Relative abundances of vertebrate taxa in Iharkút. A. NISP distribution is calculated  
2100 from only the isolated bones material of Iharkút mine. B. MNI distribution includes the  
2101 macro- and microfossils and skeletal elements of *Hungarosaurus tormai*.

2102

2103 **Figure 7.** The percentages of small (<5 cm), medium (5–10 cm) and big (10–50 cm) elements  
2104 that are over- and underrepresented compared to their expected number in the fossils material.  
2105 The expected numbers of observed elements are calculated from data of Table 4.

2106

2107 **Figure 8.** Shape sorting of the Iharkút bone assemblage based on the method of Frostick and  
2108 Reid (1983).

2109

2110 **Figure 9.** Abrasion stages of isolated bones from the site SZ-6, Iharkút without bone pebbles  
2111 and microvertebrates. A. Distribution of abrasion in the vertebrate assemblage. B. Abrasion  
2112 stages of bones between aquatic/semiaquatic and terrestrial taxa. C. Abrasion stages among  
2113 different bone sized. D. Abrasion stages of bones among the main sauropsid taxa.

2114

2115 **Figure 10.** *In situ* breakage. Turtle limb bone in anterior, A. and medial, B. views.

2116

2117 **Figure 11.** Weathering stages of bones from the site SZ-6 Iharkút, (only 15% of the identified  
2118 isolated bones, see text). A. Distribution of weathering stages in the SZ-6 vertebrate  
2119 assemblage. B. Weathering profiles limited to the isolated bone of SZ-6 assemblage.

2120

2121 **Figure 12.** Breakage distribution of bones in the SZ-6assemblage. A. distribution of breakage  
2122 types. B. Breakage stages of bones compared between aquatic/semiaquatic and terrestrial  
2123 taxa. C. Presence or absence of epiphyses on limb bones in the Iharkút material.

2124

2125 **Figure 13.** Quarry map of the 2<sup>nd</sup> (holotype) skeleton of *Hungarosaurus tormai* (meaning of  
2126 the numbers see in Supplementary Information 2).

2127

2128 **Figure 14.** Quarry maps of *Hungarosaurus tormai* skeletons of from the Iharkút locality  
2129 (meaning of the numbers see in Supplementary Information 2). A. 3<sup>rd</sup> *Hungarosaurus* skeletal  
2130 material. B. 4<sup>th</sup> *Hungarosaurus* skeletal material. C. 5<sup>th</sup> *Hungarosaurus* skeletal material.

2131

2132 **Table 1.** List of the Late Cretaceous vertebrate fauna from Iharkút.

2133

2134 **Table 2.** Classification of the taphonomic modes in the Iharkút bone assemblage based on  
2135 taphonomic dataset (See Supplementary Information 2).The characters of the table were  
2136 separated after Csiki et al. (2010).

2137

2138 **Table 3.** NISP and MNI values as well as fragmentation rate associated with taxa in the  
2139 Iharkút vertebrate locality (the NISP and fragmentation rate are calculated from only the  
2140 isolated bones material).

2141 **Table 4.** Skeletal completeness data in the Iharkút vertebrate assemblage. The MNI is  
2142 calculated from the isolated bones material of site SZ-6. Size and shape category see  
2143 subchapter of 6.3.2 and 6.3.3 and their figures and tables. \*Only turtle plate fragments which  
2144 were identified as part of a carapax or plastron. \*\*The crocodyliform vertebrae were not  
2145 separated as cervical, dorsal or caudal vertebrate in this table, because there is not enough  
2146 information about the expected number of these elements in the original skeleton as well as  
2147 due to the impossibility of distinguishing the vertebrae of different crocodyliform taxa.

2148 **%R<sub>i</sub>**: percentage of relative proportion of element i in population of MNI; **A<sub>i</sub>**: actual number  
2149 of element i in the collection; **E<sub>i</sub>**: expected number of element i in a complete skeleton per  
2150 individual; **MNI**: minimum number of individuals; **%TC<sub>t</sub>**: percentage of total skeletal  
2151 completeness of taxon t;  $\sum A_t$ : actual number of skeletal elements of taxon t;  $\sum E_t$ : expected  
2152 number of elements in a complete skeleton of taxon t

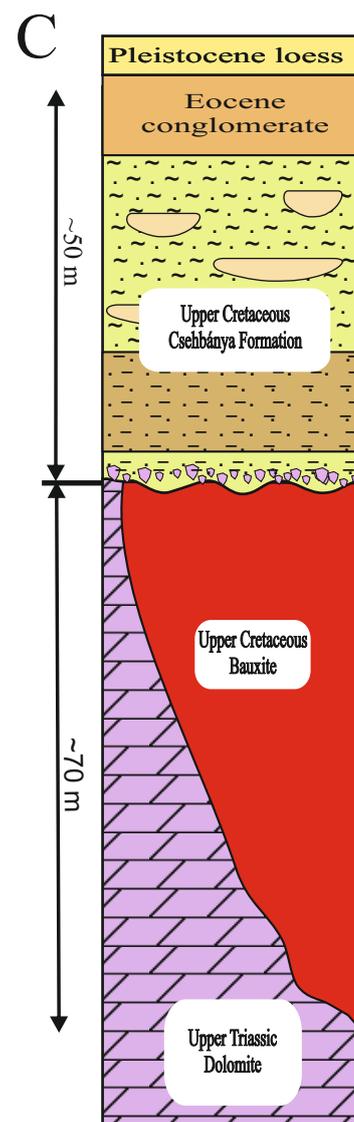

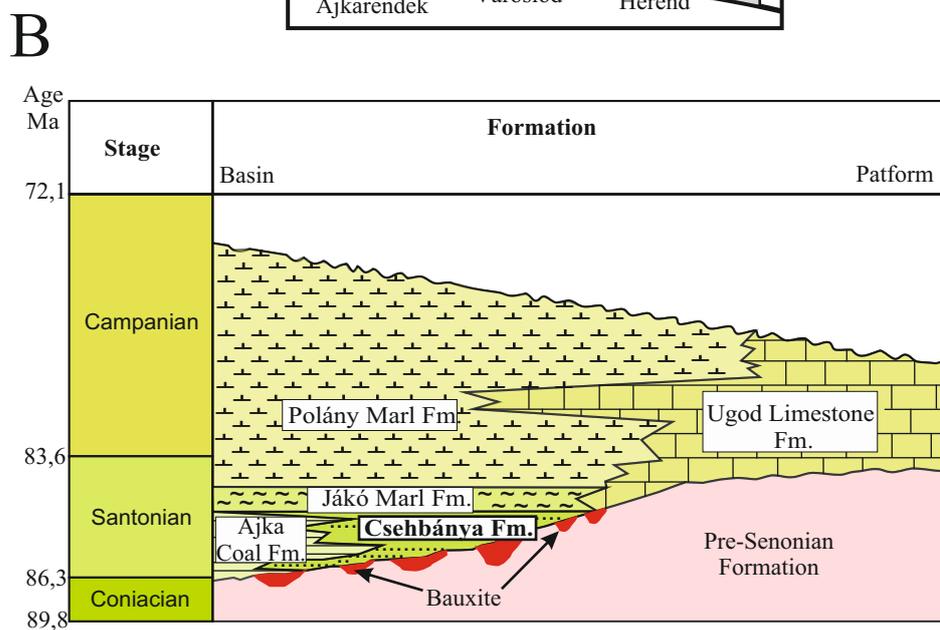

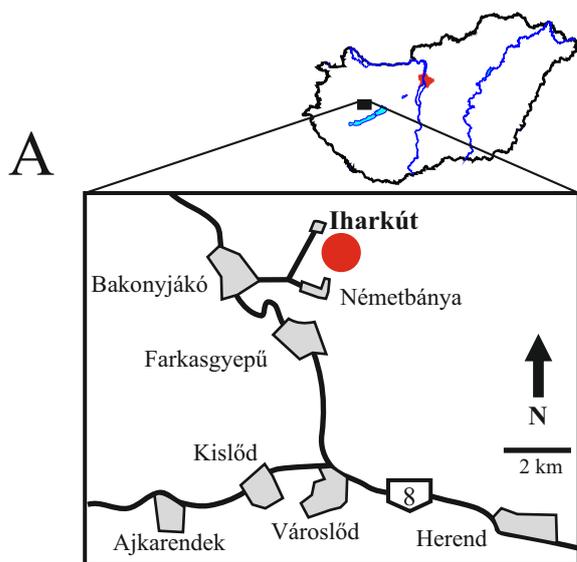

2153

2154

2155 **Table 5.** Shape sorting data of isolated bones for six sauropsid taxa associated with their  
2156 expected values at SZ-6 assemblage. Expected number of elements was adopted from Table 4.  
2157 The easily moveable shape categories are spherical and rod-like fossils, while hardly  
2158 moveable are disc- and blade-like bones based on empirical observations of Frostick and Reid  
2159 (1983).

	<i>Albanerpeton</i> sp.	cranial and mandible elements	Szentesi et al., 2013
Turtles	<i>Foxemys trabanti</i>	complete and partial skulls, mandibles, vertebrae, pectoral and pelvic girdle elements, limb bones, plastron and carapax fragments	Rabi et al., 2011
	<i>Kallokibotion</i> sp.	shell fragments	Ősi et al., 2012b
	Dortokidae indet.	shell fragments	Ősi et al., 2012b
Squamates	<i>Pannoniasaurus inexpectatus</i>	cranial and mandibular elements, teeth, vertebrae, ribs, pelvic girdle elements, limb bones	Makádi et al., 2012
	<i>Bicuspidon</i> aff. <i>hatzeiensis</i>	fragmentary mandibles, maxillae	Makádi, 2006
	<i>Pelsochamops infrequens</i>	fragmentary dentary, dentary fragments	Makádi, 2013a
	<i>Distrodon rhomboideus</i>	dentaries, maxilla	Makádi, 2013b
	Scincomorpha indet. 1	fragmentary mandible	Makádi L., pers comm.
	Scincomorpha indet. 2	fragmentary dentary	Makádi L., pers comm.
	Scincomorpha indet. 3	fragmentary dentary	Makádi L., pers comm.
	Scincomorpha indet. 4	fragmentary dentary	Makádi L., pers comm.
	<i>Doratodon</i> sp.	teeth, jaw fragment	Ősi et al., 2012b
	? <i>Theriosuchus</i> sp.	teeth, cranial elements	Rabi M., pers comm.
	? <i>Allodaposuchus</i> sp.	teeth, jaw fragments, cranial elements	Rabi M., pers comm.

Crocodiles	<i>Iharkutosuchus makadii</i>	complete and partial skulls, mandibles, various cranial elements, teeth	Ősi et al., 2007; Ősi, 2008a; Ősi and Weishampel, 2009
	<i>Bakonydraco galaczi</i>	premaxilla, complete mandible, 56 mandibular symphyses	Ősi et al., 2005; Ősi et al., 2011
Pterosaurs	Azhdarchidae indet.	cervical vertebrae, pelvic girdle elements, limb bones	Ősi et al., 2005 and 2011
	Pterodactyloidea indet.	3 mandibular symphyses	Prondvai E., pers comm.
Dinosaurs (including birds)	Tetanurae indet.	teeth	Ősi et al., 2010a
	Abelisauridae indet.	limb bones	Ősi et al., 2010a, Ősi and Buffetaut, 2011
	<i>Pneumatoraptor fodori</i>	scapulocoracoid	Ősi et al., 2010a
	Paraves indet.	teeth, caudals, limb bones	Ősi et al., 2010a, Ősi and Buffetaut, 2011
	<i>Bauxitornis mindszentyaie</i>	tarsometatarsus	Ősi, 2008b, Dyke and Ősi, 2011
	Enantiornithes indet.	limb bones	Ősi, 2008b, Dyke and Ősi, 2011
	<i>Hungarosaurus tormai</i>	6 associated and 1 articulated partial skeletons, associated and isolated cranial and mandibular elements, teeth, vertebrae, ribs, pectoral and pelvic girdle elements, limb bones, osteoderms	Ősi, 2005, Ősi and Makádi, 2009
	cf. <i>Struthiosaurus</i> sp.	humerus	Ősi and Prondvai, 2013
	<i>Mochlodon vorosi</i>	cranial and mandibular elements, teeth, vertebrae, pectoral and pelvic girdle elements, limb bones	Ősi et al., 2012a
	<i>Ajkaceratops kozmai</i>	cranial and mandibular elements	Ősi et al., 2010b

**Table**  
[Click here to download Table: Botfalvai et al\\_Table 2.pdf](#)

code	Taphonomic modes	Description	Number of elements in the dataset (2013)	Taxonomic composition	Taphonomic features	Interpretation	Lithological situation and site
1	<i>Isolated bones</i>						
1.1	bone pebbles	Small-sized, high abraded bone fragments	4018 specimens	Taxonomically and/or anatomically unidentified	Highly abraded and fragmented	Interpreted as coarse-grained particles of the bed-load of the ancient stream. These are common bone preservation forms in the channel-lag deposit (Behrensmeyer 1988)	Ubiquitous elements, but are very common in the basal breccia of the SZ-6 site
1.2	"single" isolated bone elements	Well- and medium-preserved isolated bone elements which are defined as a single element in each skeleton (e.g. scapula, femur, humerus etc.)	4225 specimens	High diversity assemblages, all taxa are represented within	Usually well-preserved, often broken and abraded but rarely weathered	Short-distance transported bones	Ubiquitous elements, but are very common in the layers of the SZ-6 site
1.3	"complex" isolated skeletal elements	Skeletal elements which are preserved as ossified multiple bones (e.g. skull, mandible, synsacrum of ankylosaurs)	9 mandibular, 10 skulls, 9 ankylosaur sacral regions and 1 rhabdodontid sacral region	Lower diversity assemblages, turtles ( <i>Foxemys</i> ), crocodiles ( <i>Iharkutosuchus</i> ), dinosaurs ( <i>Hungarosaurus</i> , <i>Mochlodon</i> ), and pterosaurs ( <i>Bakonydraco galaczi</i> ) are represented in this group	Usually well-preserved, sometimes broken and abraded	Not or short-distance transported bones	Rare elements in the assemblages, occurrence is confined to the layers of the SZ-6 site
1.4	Teeth	Well- and medium-preserved isolated tooth elements	2259 specimens	High diversity assemblages	Usually well-preserved	The mode of accumulation of teeth is different than that of the bones (Behrensmeyer, 1975; Argast et al., 1987; Fiorillo, 1991)	Ubiquitous elements in all of the bone beds of the Iharkút site
2	<i>Microfossils</i>	Well- and medium-preserved isolated bone elements, representing animals whose body weight was <1kg (Behrensmeyer et al., 1979)	358 specimens	High diversity assemblages, almost every taxon of the macrofauna as well as frogs, small lizards and Albanerpetontidae are represented in this group	Well-preserved but fragmentary assemblages. The teeth are usually missing from the dentary, premaxilla or maxilla	Most of the microfossils were transported for a short time before accumulation	Most of them were obtained by screen-washing from SZ7-8 and SZ-6 site
3	<i>Associated skeletal elements</i>	Bones and teeth which are isolated and separated from each other but belong to the same skeleton (Lyman, 1994a)	595 specimens of six individuals	Ankylosaurs	Well-preserved but fragmentary assemblages. There is evidence for occurrences of in situ breakage by trampling	Size and taphonomic features of these bones remain indicated that they were not transported with the sediment clasts or isolated elements. Instead, these assemblages accumulated at the site by carcass floating or during a subsequent event	They were discovered from the SZ-6 site
4	<i>Articulated skeleton</i>	Elements of the skeleton found in the same anatomical position as in the living organism (Badgley, 1986a)	Hip region of one individual	Ankylosaurs	There is evidence for occurrences of in situ breakage by trampling	This assemblage accumulated at the site by carcass floating or during a subsequent event	It was discovered in the basal breccia of SZ-6 site

**Total elements in the Iharkút dataset (See supplementary information 2)**

**11493**
