Running title: The fate of phosphorus in decomposing fish carcasses

Keywords: fish, decomposition, phosphorus, algal bloom, mesocosm
Summary

An outdoor mesocosm experiment was conducted to study the process of phosphorus (P) and nitrogen (N) release during fish carcass decomposition and its implications for the functioning of warm, shallow temperate lakes after massive fish kills. Specifically, we compared differences in the fate of P released from carcasses of two fish species that differ in body P concentrations, and the ecosystem responses to these fish-derived nutrient inputs.

Nutrients liberated from bluegill (Lepomis macrochirus) and gizzard shad (Dorosoma cepedianum) carcasses induced phytoplankton blooms, and high total P and N concentrations in the water column within a week after carcass addition; these effects persisted for ~2–3 weeks. Subsequently, water column P was transferred to other ecosystem compartments, primarily sediments and benthic algae.

Fish species identity influenced the effects only slightly; decomposition of gizzard shad triggered the highest maximal chlorophyll-α concentrations in the water column, while the highest coverage of benthic algae and lowest biomass of periphytic biofilm were found in mesocosms containing bluegill carcasses.

Both bluegill and gizzard shad carcasses decomposed completely during the experimental period (~3 months). Thus, apparently all carcass nutrients were mineralized into bioavailable forms and taken up by other ecosystem compartments.

Fallen fish carcasses are not likely to represent long-term P sinks in warm-temperate shallow lakes. Decomposition following large mortality events can induce fleeting algal blooms in these ecosystems.
Introduction

Fish can affect the nutrient cycles of freshwater ecosystems through several direct and indirect mechanisms, including nutrient regeneration, translocation of nutrients within and among ecosystems, storage of nutrients in bodies, carcass decomposition and cascading trophic interactions (Vanni, 2002; Vanni, Boros & McIntyre, 2013). However, the mechanisms by which fish affect nutrient dynamics, their relative importance and their net effects on primary producers continue to be a topic of debate (Sereda & Hudson, 2010). Fish often constitute a considerable nutrient pool (Kitchell, Koonce & Tennis, 1975; Sarvala & Jumppanen, 1988; Griffiths, 2006) that is unavailable to other organisms (except piscivores and parasites) as long as it remains in living biomass. In other words, nutrient sequestration by fish may reduce nutrients available to other organisms. Some authors suggest that fish are important nutrient sinks (Griffiths, 2006; Sereda et al., 2008), because of the relatively long turnover time of the elements stored in their bodies. However, many other studies show that nutrient translocation and excretion by fish can be an important source of nutrients for primary producers and microbes (e.g., Vanni, 2002; Zimmer, Herwig & Laurich, 2006; McIntyre et al., 2008).

A recent analysis suggests that the fate of fish carcasses is critical in determining the extent to which fish are nutrient sinks or sources (Vanni et al., 2013). Under natural conditions, massive mortality events (“fish kills”) can occur for many reasons, including oxygen depletion, starvation, diseases or toxins. When fish die and decompose, nutrients previously sequestered in fish biomass become available for primary producers, but the rates and ratios at which these nutrients are made available are largely unknown (Parmenter & Lamarra, 1991; Vanni et al., 2013). Besides turnover time, the turnover rate of fish-bound elements is also significant when assessing the role of fish as sinks or sources of nutrients. Fish decomposition can provide considerable amounts of limiting nutrients that ultimately influence the structure and functioning of aquatic ecosystems, especially in the case of mass mortality events (Parmenter & Lamarra, 1991; Premke et al., 2010). Alternatively, because a sizeable fraction of fish phosphorus (P) is tied up in relatively recalcitrant structures such as bones and scales, mineralization of carcasses may take years and provide a small but steady source of nutrients (Kitchell et al., 1975). In fact, natural fish mortality and consequent nutrient release has the potential to generate fluxes of mineralized nutrients to the water column at levels comparable to loading by other major nutrient sources. For instance, Kitchell et al. (1975) calculated that late spring and early summer bluegill (Lepomis macrochirus) mortality represents a flux of mineralized P to the water column at rates higher than allochthonous inputs in a Wisconsin lake. Moreover, Nakashima & Leggett (1980) pointed out that nutrient release due to fish decomposition was equivalent to 20% of the allochthonous P entering the southern basin of Lake
Memphremagog (USA/Canada) in the spring. Durbin, Nixon & Oviatt (1979) also found that the influx and mortality of alewives (*Alosa pseudoharengus*) had considerable impact on the food chain and nutrient cycles in the Pausacaco Pond (RI, USA), causing 0.43 g m$^{-2}$ P and 2.7 g m$^{-2}$ N loading over a 2-month period. On the other hand, Chidami & Amyot (2008) assessed that water-to-sediment deposition of white sucker (*Catostomus commersonii*) carcasses alone corresponds to about 13.5% of the annual particulate P sedimentation in the east basin of Lake Croche (Canada), representing a potential loss of nutrients from the pelagic food web but a potential nutrient source to the benthic food web.

Despite the potential importance of fish decomposition for internal nutrient cycling, relatively little is known about the fate of P released from or retained in decaying carcasses (Vanni et al., 2013). Bones and scales of fish contain considerable P (Rønsholdt, 1995; Hendrixson, Sterner & Kay, 2007) in the form of hydroxyapatite (Schenau & De Lange, 2000). In fact, 86–88 % of body phosphorus content is stored in the skeleton of teleost fish (Rønsholdt, 1995). These tissues may be recalcitrant and resist rapid degradation (Claeson et al., 2006) resulting in long-term P retention in sediments; indeed fish bones and scales are sometimes present as fossils (Trueman & Marill, 2002). Because P is often a dominant limiting nutrient in controlling phytoplankton production (Schindler, 1977; Lewis & Wurtsbaugh, 2008), the rate of P liberation from decomposing fish could have important ecosystem-level implications and determines the role of fish as sinks or sources of P.

The elemental composition of fish varies considerably among taxa (e.g., Czamanski et al. 2011) due to the differences in their anatomy (Hendrixson et al. 2007). Thus, the possible interspecific differences in the relative proportions of hard structures in fish bodies, such as bones or integuments (rich in P), may yield varied rates of decomposition among fish species (Hendrixson et al. 2007). Most studies on fish decomposition have been restricted to salmonids (e.g. Parmenter & Lamarra, 1991; Schuldt & Hershey 1995; Cederholm et al., 1999; Claeson et al., 2006; Bretherton et al., 2011), which represent only a small fraction of fish diversity. In addition, the vast majority of fish decomposition studies have focused on either the loss of total body mass during decomposition or the fate of visible carcasses (e.g. Schneider, 1998; Premke et al., 2010), rather than explicitly examining nutrient mineralization during fish decomposition. Yet, decomposing fish can mineralize much of their nutrient content quickly. For instance, Parmenter & Lamarra (1991) found that rainbow trout (*Oncorhynchus mykiss*) carcasses decomposing in a Wyoming freshwater marsh lost 80% of their original nitrogen (N) but only 50% of the original P content after 15 to 30 days, and 95% of their original N and 60% of their original P after 10 months. They highlighted the fact that 40% of the total fish P remained immobilized in bones and scales, and suggested fish carcasses can function as source of N but as a partial sink for P. Notably,
the long-term fate of bone and scale P is not known, and the P-mineralization rates in their study may have been low due to cold water temperatures (4 – 14 °C in bottom waters where fish decomposed). Chidami & Amyot (2008) also quantified decomposition rates of rainbow trout in a boreal lake (temperature 6 – 22 °C) and found that decomposition rates were rapid in shallow and warm regions where carcasses were exposed to scavenging, but slower in deep waters where decomposition was driven primarily by bacteria. The scarcity of data and the variability among the results of previous studies on fish decomposition renders it difficult to draw overall conclusions about the role of fish as nutrient sources or sinks.

Recent models exploring whether fish are P sources or sinks in lakes show that the net role of fish in nutrient cycles depends on the rate at which fish carcass P is mineralized, the spatial scale of interest (i.e., whether fish are sources or sinks for the benthos, water column, or entire ecosystem) and the fate of mineralized P (Vanni et al., 2013). To elucidate the fate of P during fish decomposition in freshwater ecosystems, we conducted an outdoor mesocosm experiment that simulated massive summer fish kills in a warm-temperate shallow lake. Moreover, we explored interspecific differences in P release rates and fates from decomposing carcasses using carcasses of two fish species that differ in body P content (as % dry mass). We had two main hypotheses. First, we hypothesized that a majority of fish carcass nutrients (from both species) would rapidly become available to primary producers, and be quickly integrated into the food web, in warm, oxygenated water. Second, we hypothesized that a greater fraction of body P would be mineralized from the low-P species (gizzard shad: Dorosoma cepedianum) than carcasses of high-P species (bluegill: Lepomis macrochirus) and result in more intense phytoplankton blooms. This prediction was based on the assumption that low-P species contain a greater fraction of body P that is labile (e.g., as RNA or phospholipids) and a smaller fraction that is recalcitrant (i.e., bones and scales).

Methods

Experimental design

We conducted an outdoor, mesocosm experiment between 15 June and 11 September 2012 at the Ecology Research Center of Miami University (Oxford, OH, USA). Each of the nine mesocosms (Fig. 1a) had a volume of 5 m³, a bottom area of 4 m², and a water depth of 1.2 m. We added a 5 cm layer of dried sediment that was collected from eutrophic Acton Lake (OH, USA) to the bottom of each tank, and filled them with 4.8 m³ of water from a nearby mesotrophic pond. Water was circulated in the tanks with an air-lift mixing system (González, Knoll & Vanni, 2010). This system prevented stratification and circulated the upper layer of the water column by
inducing slow currents, but did not pump air directly into the mesocosms. We applied three different treatments, each replicated in three randomly selected mesocosms: bluegill carcasses (BG treatment), gizzard shad carcasses (GS treatment) and control (no fish). To realistically simulate a massive fish kill, we assumed 500 kg ha$^{-1}$ fish biomass and 80% mortality; thus we added $\sim$400 kg ha$^{-1}$ (wet mass) of fish to the BG and GS treatments (160–170 g fish per mesocosm). While this biomass is relatively high, it is within the range observed in nearby eutrophic reservoirs (Hale et al., 2008). We added 15–20 carcasses to BG tanks (wet mass of individual carcasses: 8.9±4.4 g; total length: 75±13 mm) and two carcasses per GS tank (wet mass: 84.7±9.4 g; total length: 200±9 mm). Fish size was determined by availability in Acton Lake, where we collected fish for this experiment.

Carcass inputs were equal to 1.2 g P loading per mesocosm in the BG and GS treatments (Table 1), or 250 µg P L$^{-1}$. To determine the amount of P we added in fish carcasses, we analyzed the body P contents of a sample of fish collected at the same time and in the same manner as fish added to mesocosms (Table 1).

In the BG treatment, three bluegill carcasses per tank were placed in polystyrene weighing dishes (10 cm in diameter and 3 cm depth), covered with mosquito netting (Fig. 1c), and embedded into the sediments. This method was applied to help find and identify visible fish fragments at the end of the experiment. However, we used these trays only on a subset of carcasses, because we were unsure if the fate of carcasses would be the same inside and outside the trays. Gizzard shad carcasses were tagged with cable ties threaded through the opercular opening (Fig. 1b) to facilitate finding carcass remains in sediments at the end of the experiment. Because we added only two carcasses per tank in the GS treatment, we chose not to use the trays in this treatment.

One of our primary goals was to assess the availability and fates of fish carcass P in the mesocosms. Therefore, we traced the flow of fish carcass P into the water column, the benthic organisms growing on the sides and bottoms of the mesocosms and in the sediments.

Sampling

Water column N, P and chlorophyll-$a$ were sampled weekly with a plastic tube sampler (5.5 cm diameter) lowered into the water column. Water column chlorophyll-$a$ was quantified as a measure of the bioavailability of carcass nutrients and to gauge the response of phytoplankton to carcass decomposition. Temperature and dissolved oxygen were also monitored weekly 30–40 cm above the sediment surface, using a YSI Pro20 oxygen meter (YSI Inc., OH, USA), to determine if temperature was similar among treatments and to see if fish decomposition occurred in an oxic or anoxic environment.
To estimate the flux of P from carcasses to other ecosystem compartments, we quantified total P in the water column, on mesocosm walls, in benthic algae and in the sediments. To assess P flux to mesocosm walls, plastic strips (5.5 × 8.5 cm) were fixed on the walls at three depths and in all four cardinal directions (12 strips per mesocosm) to assess P uptake via biofilm growth during the course of the experiment. At the final sampling in September, the plastic strips were collected, biofilm was scraped off and the total biomass of biofilm on strips was calculated and extrapolated to the entire inner wall surface (8.48 m²) of mesocosms. Subsamples of biofilm taken at the final sampling were used to estimate P content. To assess P flux to benthic algae, three samples were collected from random locations in each tank with a plastic tube sampler (15 cm diameter); the measured biomasses were averaged and converted to the bottom area of the mesocosms (4 m²) by extrapolating coverage (%) in samples to total biomasses of benthic algae per mesocosm. To quantify P flux to sediments, three samples of the entire sediment depth (excluding benthic algae on the sediment surface) were collected with the same tube sampler mentioned above, prior to the experiment’s start in June and at the final sampling to quantify initial and final sediment P pools, to explore changes in chemical composition and to search for visible fish remnants or scavengers. In addition, in GS treatments, we collected sediment samples from locations where fish decomposed (identified by the presence of cable ties; Fig. 1b) and those not near carcasses, so we could compare P concentrations in sediments in those locations. At the end of the experiment, polystyrene weighing dishes containing bluegill carcasses (Fig. 1c) were collected from the bottoms of BG mesocosms to inspect if they contained any visible fish remnants or if all fish-derived material decomposed during the experimental period.

Sample processing and analytical methods

To estimate initial fish body (carcass) P content and P input to the mesocosms, whole carcasses were dried to a constant weight at 60°C, then coarsely ground with a coffee mill and finally ground to a fine powder with a Retsch ZM100 centrifugal mill (Retsch GmbH, Germany). Sediment, benthic algae and biofilm samples used to estimate P pools were ground with a mortar and pestle prior to P-content analyses. P concentrations were measured with a Lachat QC 8000 FIA autoanalyzer (Lachat Instruments, CO, USA) following the digestion of samples at 550 °C and 1N HCl solution (e.g. Vanni et al., 2002; 2011). Water column total N and P was also measured with the auto-analyzer, following potassium persulphate digestion. Chlorophyll-a was measured with a fluorometer following extraction in ethanol.

Statistical methods
Differences in temperature, dissolved oxygen, total P and chlorophyll-\(a\) content of the water column within and among treatments were analyzed by using one-way ANOVA tests combined with Tukey’s pairwise comparisons. These comparisons were done on each sampling date because we wished to know if and when carcass-derived nutrients could be detected in the water column. Kruskal-Wallis tests and one-way ANOVA tests were used to reveal the differences between treatments in biomass and coverage of benthic algae, biomass of biofilm and total P content of sediment samples. Statistical analyses were performed using PAST 2.17 (PAleontological STatistics, Norway), and decisions about the statistical significances were set at \(P=0.05\) level.

Results

Both water temperature and dissolved oxygen exhibited similar dynamics in all treatments during the course of the experiment and significant differences were not observed among treatments (ANOVA, Tukey’s post-hoc test; \(P > 0.05\) on all dates). Water temperature varied between 18.7 and 29.3 °C (avg. ± SD; 24.5 ± 2.9 °C), while dissolved oxygen ranged from 7.5 to 10.2 mg L\(^{-1}\) (Table 2).

Total phosphorus (TP) in the water column did not differ significantly (\(P > 0.05\)) among treatments on the first sampling date (44.7 ± 7.2 µg L\(^{-1}\) in the mesocosms) prior to fish carcasses being placed in the mesocosms. However, after one week, TP was significantly higher in treatments with fish carcasses, increasing by ~50 µg L\(^{-1}\) during this period in each mesocosm; this corresponds to 20% of the P added as carcasses. Peak values of TP were observed one week after carcass addition: 95.8±7.6 µg P L\(^{-1}\) in BG treatment and 98.6±5 in GS treatment, more than 2.5-times greater than the control (38.3±8.0) on the same sample date. Total P levels were significantly greater in the mesocosms containing fish carcasses for two more weeks, but by week 5 there were no further differences among treatments (Fig. 2a). There was no significant difference in TP between the two fish species treatments throughout the experiment (Fig. 2a). Total nitrogen (TN) in the water column exhibited a similar pattern, peaking one week after carcass addition (939.0 ± 70.3 and 865.4 ± 55.9 µg L\(^{-1}\), respectively) in both the BG and GS treatments. The high-TN period persisted for three weeks, and after week 5, there were no significant differences between treatments except for the last sampling date when TN increased markedly in the GS treatment (Fig. 2b).

Chlorophyll-\(a\) dynamics in the water column were similar to those of TP and TN; chlorophyll concentration was the greatest one week after carcass additions in treatments with fish (41.9±12.04 µg L\(^{-1}\) and 50.3±10.4 4 µg L\(^{-1}\) in BG and GS mesocosms, respectively). These values were 5.5−6.5-times higher than those of the controls at the same time (Fig. 2c). The highest mean chlorophyll-\(a\) levels were detected in the GS treatment, but the difference
was significantly greater than the BG treatment only in week 2. From week 4 on, there were no significant differences in chlorophyll-a among any treatments (Fig. 2c).

By the end of the experiment, the bottoms of all mesocosms were covered with benthic algae to various extents (Fig. 1d; Fig. 3a,b). Submerged macrophytes did not develop in the mesocosms, except in one of the control tanks where a shoot of *Myriophyllum* sp. was found (this was included in the pool of benthic algae). Biomass of benthic algae (dry mass) varied between 108 and 507 g m⁻², with coverage between 50–100 % (Fig. 3a,b). Biofilm growth occurred on the walls of all tanks (Fig. 1d; Fig. 3c). It consisted mainly of ball-shaped “jelly” bubbles formed by cyanobacteria (*Rivularia* sp.) embedded in a gelatinous matrix. The wet mass of this periphytic biofilm was relatively high (between 0.18–1.8 kg m⁻²), but due to its very low P content and high water content (98.1±0.9 %), it did not constitute a large P pool (Tables 1 & 3). The BG treatment had the lowest biofilm mass (Fig. 3c), which differed significantly from the other two treatments (*P* < 0.05 in both cases). Biofilm dry mass did not differ significantly between GS and control treatments (*P*=0.44).

P content of sediments at the end of the experiment did not differ significantly among treatments (*P* > 0.05, Kruskal-Wallis tests; Fig. 4a). Furthermore, P content of sediments taken from locations where fish decomposed and from other, randomly selected locations in the GS tanks did not differ (*P* > 0.05; Fig. 4b). All sediment samples taken at the end of the experiment were visually analyzed for carcass remnants and scavengers. We could not detect any fish remnants in sediments; thus virtually all carcasses decomposed completely during the experimental period. Notably, we did not find any potential scavengers in the sediment samples. Contents of polystyrene weighing dishes from the BG treatment were visually analyzed and fish remnants were not found in them; the weighing dishes contained only settled detritus.

To better evaluate the fate of carcass P, we constructed P budgets for the mesocosms (Table 3). Sediments were by far the largest P pool in the mesocosms (> 98% of total P mass in all mesocosms). We observed a slight increase in the total mass of P in the mesocosms (mostly in sediments); however, the difference between the initial and final P pools was less than 2.3% in all cases, and initial and final total mesocosm P mass did not differ significantly among treatments (*P* > 0.05 in all cases).

**Discussion**

Our results demonstrated that nutrients liberated from the decomposing carcasses of fish can stimulate phytoplankton blooms and high TP and TN concentrations in the water column. Total P increased considerably in the water column one week after fish addition and corresponded to the remineralization of 20% of the P added
as carcasses, suggesting that a large fraction of carcass P was released directly into the water column. The intensive algal bloom that occurred in both of the fish treatments lasted only 2–3 weeks, and correlated with high water-column P. Similar results were obtained by Durbin et al. (1979) who also reported a large, but short-lived, phytoplankton bloom after carcass addition in a mesocosm experiment. These dynamics suggest that under these conditions, a significant fraction of the P stored in fish carcasses becomes available to primary producers within a relatively short time.

TN exhibited a trend similar to TP, with a remarkable increase one week after carcass addition, and with significantly higher TN values in the BG and GS mesocosms for two more weeks. Parmenter & Lamarra (1991) reported that 80% of the original N content of fish carcasses was released within one month, presumably because the vast majority of body-N content is stored in soft tissues such as muscle (Pangle & Sutton 2005; Vrede et al. 2011) that decompose and release nutrients relatively rapidly. Interpreting N dynamics using budgets is more problematic than for P because of processes such as N fixation, nitrification and denitrification. Nevertheless, we can presume that decomposition-derived nutrients elevated N levels after carcass addition.

The decrease in water column P and associated increase in benthic algal P show that P taken up in the initial phytoplankton bloom became unavailable to water-column organisms in a relatively limited period of time. Dissolved oxygen levels were consistently high (> 7.5 mg L⁻¹) above the sediment surface in all mesocosms throughout the experiment (Table 2), and we presume that these conditions in the overlying water might have kept redox potentials high enough in sediments to retain P permanently (i.e., anoxia and low redox potentials in sediments are not likely to occur when the overlying water is saturated with oxygen) (Boström, Jansson & Forsberg, 1982). Thus, redox-dependent P retention in sediments might have played an important role in reducing P and consequently chlorophyll levels in the water column. There was no significant difference in sediment P content across treatments, but this is probably because the amount of P added as fish carcasses was very small compared to the size of the sediment pool (Table 3). In addition, a considerable mass of benthic algae had started to develop in all mesocosms 2–3 weeks after the experiment’s start, which sequestered P and facilitated P retention in sediments by oxygenating the upper sediment layers and consequently by raising redox potential (Scheffer, 1998; Dodds, 2003; Zhang et al., 2013).

We recognize that the distribution of habitats (water column, sediments, vertical benthic structures) in our mesocosms differs from that in a lake and that decomposition in our mesocosms occurred in absence of scavengers. Thus, in an actual lake ecosystem, the distribution of carcass-derived nutrients into various ecosystem compartments may differ from what we observed, and will be strongly influenced by factors such as
ecosystem size and productivity (e.g., the relative areas and productivity of littoral vs. pelagic regions). However, we can infer that any P transferred from carcasses to the pelagic zone or to mesocosms walls must have first been converted to a bioavailable (presumably dissolved inorganic) form. Thus, in an actual lake ecosystem, with similar conditions, these nutrients would be available to benthic and/or pelagic primary producers and carcasses would not represent nutrient sinks. Thus, it is potentially instructive to discuss the factors that may have influenced P fluxes among compartments.

Both average biomass and coverage of benthic algae tended to be higher in treatments containing fish carcasses, although the only significant difference occurred in coverage between BG and the control treatments (Fig. 3b). Biofilm growth on the inner walls of mesocosms was similar in GS and control treatments, and was considerably lower in BG treatment. However, because the biofilm was a relatively small P pool (Table 3), we assume that it had negligible effect on phytoplankton via nutrient competition. In lakes, competition for P between benthic algae and phytoplankton influence the fate of carcass P. For example, if benthic primary producers account for a large fraction of total primary production (as might occur in small shallow lakes, or in clear lakes; Vadeboncoeur et al., 2008), a large fraction of carcass P may be redistributed to benthic producers, particularly if they are good P competitors compared to phytoplankton. Alternatively, in deep lakes, profundal scavengers could sequester much of the carcass P; the subsequent fate of this P may depend on the extent to which these scavengers move P to other habitats and/or are consumed by mobile consumers such as fish.

Using two fish species enabled us to study interspecific differences in decomposition rates and associated P fluxes. Even though bluegill and gizzard shad differ in P content (Torres & Vanni, 2007; Table 1), probably due to their differing anatomical features (Hendrixson et al., 2007), we did not observe large differences in TP levels in the water column, sediments or other pools between treatments containing the two different fish species. Treatments differed significantly in peak phytoplankton (chlorophyll-a) concentrations (highest in GS mesocosms) (Fig. 2) and in the coverage of benthic algae (higher in BG mesocosms than in the controls) (Fig. 3). The amount of carcass P input was nearly equal in both fish treatments, and we expected that gizzard shad carcasses may trigger higher P levels in the water column as they are less “bony” than bluegills, and consequently a higher proportion of body P of gizzard shad could be liberated more effectively and rapidly. This assumption was partially supported by the chlorophyll results, although a difference in water column TP levels was not detectable between BG and GS treatments (Fig. 2). On the other hand, decomposition of bluegill carcasses promoted the development of the highest coverage of benthic algae, indicating some variance in ecosystem responses to the decomposition of different species. While the difference in body P between our two
species (3.1 vs. 2.6% of dry mass) may seem relatively small to elicit different ecosystem responses, it could easily have resulted in large differences in P dynamics. For example, if we assume that non-bone P comprises 0.9% of dry mass (Hendrixson et al., 2007), the amount of non-bone P added to mesocosms in the GS and BG treatments would have been 87 and 73 µg P L⁻¹ (the mass of bone-P would have been 163 and 177 µg P L⁻¹, respectively). Thus, substantially more non-bone P was added in the GS treatment than in the BG treatment, expressed per volume of mesocosm water, yet water column TP dynamics were indistinguishable in the two treatments. These results, in conjunction with the apparently complete decomposition of carcasses, suggests that, under the conditions of our experiment, fish species identity as determined by body P content does not matter in terms of the fate of carcass P.

One of our primary goals was to assess whether fish carcasses decompose completely and release all sequestered P, or if a fraction of body P remains immobilized and buried in sediments permanently. We find contradictory results in the literature concerning fish decomposition; for example, Claeson et al. (2006) found that inner body tissues of salmon decomposed completely after two months in the Wind River (WA, USA), (mean water temperature between 11.4 – 12.8°C; minimum and maximum 8.9°C and 15.4°C), but some bone and skin remained intact in the long term (they did not measure nutrients in carcasses). Similarly, Premke et al. (2010) reported total decomposition of fish carcasses after 2–3 months in the pre-alpine Lake Constance, Germany (water temperature ranged between 4 – 25 °C). In contrast, Kitchell et al. (1975) and Parmenter & Lamarra (1991) showed that 40–50% of fish carcass P remained immobilized in recalcitrant materials and was stored in sediments, excluded from the active P pool of the ecosystem, at least in the short term. However, Kitchell et al. (1975) recognized that this portion of carcass P can be remineralized slowly over longer periods. Based on these studies, we hypothesized that fish decomposition would be relatively fast in our mesocosms due to the elevated water temperature (24.5 °C on average, and much higher earlier in the experiment), but that some recalcitrant, fish-derived material would act as a "permanent" P sink.

Contrary to our expectations, there was no evidence for the long-term retention of fish-derived P in sediment, as the TP content of different sediment samples (locations under carcasses vs. random locations) did not differ significantly. Furthermore, the sediment samples did not contain any visible fish remnants, suggesting that decomposition was complete in our mesocosms. Finally, bluegills in the weighing dishes apparently decomposed completely during the course of the experiment; there were no detectable remains in the dishes and we did not find any scavengers that could have removed carcass fragments. Thus, our study provides evidence that even in the apparent absence of scavengers, P stored in fallen fish carcasses can re-enter internal nutrient-cycling
pathways with high efficiency, if environmental conditions are favorable. This finding is important because recent models (Vanni et al., 2013) show that the rate at which fish carcasses decompose and liberate P is critical in determining their net role in nutrient cycles, i.e., whether they are sources or sinks of P at the scale of the ecosystem (e.g., lake) or habitat (e.g., benthic or pelagic zones). We conclude that fish are much less likely to function as P sinks in shallow, warm-temperate lakes than in deeper and/or colder lakes where a significant fraction of fish-derived P can be lost permanently from the available nutrient pool by incomplete decomposition (Kitchell et al., 1975; Parmenter & Lamarra, 1991). However, even mass mortality events occurring in winter can increase water column P and stimulate phytoplankton biomass the following spring, presumably because carcasses decompose rapidly when temperatures warm (Schoenebeck et al., 2012).

Deeper insight into the process of P release from decomposing fish carcasses is essential to better understand the complex role of fish in aquatic ecosystems. However, as Chidami & Amyot (2008) pointed out, the fate of fish carcasses after deposition at the sediment surface is still poorly documented. Our study revealed that massive fish kills can induce fleeting algal blooms in the water column of shallow lakes, and that fish species identity only slightly influences the effects. Massive fish mortality may have only temporary impacts on water quality, and after a few weeks of transition, the effects of such a large, pulsed nutrient input may dissipate, at least in terms of water column nutrients. Some authors have concluded that fish biomass can constitute a considerable P sink because fish are long-lived relative to other aquatic organisms (e.g., Griffiths, 2006; Sereda et al., 2008) and a significant fraction of body P can remain immobilized postmortem in heavily recalcitrant materials and buried in sediments (Parmenter & Lamarra, 1991). Yet, for fish to function as true nutrient sinks, the storage of nutrients in fish biomass over time must represent a permanent net reduction of the nutrients available to other organisms (Vanni et al., 2013). Our results cast doubt on the idea that fish carcasses act as permanent P sinks in shallow lakes with higher water temperature; such lakes are abundant in both temperate and tropical regions. If live fish biomass remains relatively constant, and if carcasses fully decompose and liberate all of their P (even if this occurs slowly), fish are not likely to function as ecosystem-level P sinks. The variable results regarding fish decomposition draw attention to the importance of context-dependent approaches when assessing the function of fish as sinks or sources of nutrients, and indicate a need for additional experimental and whole-ecosystem studies.

Acknowledgements
The Rosztoczy Foundation supported Gergely Boros by providing a postdoctoral fellowship to conduct research at Miami University. We acknowledge the support of NSF grant DEB 0743192. We thank E. Mette, T. Ratliff, L. P. Leon, Z. Alley and A. Morgan for assistance in the field and lab, and Ecology Research Center staff for logistical support.

Figure legends

Figure 1. Outdoor mesocosms at the Ecology Research Center, Miami University. (a) The array of mesocosms showing the deck used for sampling. (b) Gizzard shad were marked with cable ties threaded through the opercular opening, used to facilitate locating carcass remnants at the end of the experiment. (c) Bluegills in polystyrene weighing dishes prior to lowering into the sediment (rocks were included to hold dishes in place). (d) Considerable biomass of benthic algae and biofilm covered the mesocosms by the end of the experiment.

Figure 2. Time-courses of water column total phosphorus (TP), total nitrogen (TN) and chlorophyll-a during the experiment. Letters above the columns denote the significance of differences between treatments: a, no significant difference between treatments (P >0.05); b, control differs significantly from the other two treatments; bluegill and gizzard shad treatments do not differ significantly; c, gizzard shad treatment differs significantly from the other two treatments; bluegill and control treatments do not differ significantly; d, significant differences between all treatments.

Figure 3. Biomass and coverage of benthic algae, and biomass of biofilm in the three different treatments at the end of the experiment (BG – bluegill treatment; GS – gizzard shad treatment; C – control). Lower case letters above the columns denote the similarities and significant differences between treatments (treatments denoted with the same letter do not differ significantly; P≥ 0.05), while whiskers denote minimum and maximum values.

Figure 4. (a) Total phosphorus (TP) content of sediments in the three different treatments at end of the experiment, and (b) in the gizzard shad tanks where sediment cores from random locations were compared to locations where fish carcasses decomposed. The box represents the 25 and 75 % quartiles, while the band in the box denotes the mean. The whiskers represent the highest and lowest values.
