Abstract

To investigate Holocene vegetation and fire-disturbance histories in the treeline ecotone, macroscopic charcoal, plant-macrofossil, and pollen records from two lacustrine sediment records were used. Lake Lia is on the southern slope and Lake Brazi is on the northern slope of the west-east-oriented Retezat Mountain range in the Romanian Carpathians. The records were used to reconstruct Holocene fire-return intervals (FRIs) and biomass burning changes. Biomass burning was highest at both study sites during the drier and warmer early Holocene, suggesting that climate largely controlled fire occurrence. Fuel load also influenced the fire regime as shown by the rapid biomass-burning changes in relation to timberline shifts. Overall, the number of inferred fire episodes was smaller on the northern than on the southern slope. FRIs were also comparatively longer (1000–4000 years) on the northern slope where *Picea abies*-dominated woodlands persisted around Lake Brazi throughout the Holocene. On the southern slope, where *Pinus mugo* was more abundant around Lake Lia, FRIs were significantly shorter (80–1650 years). A period of frequent fire episodes occurred around 1900–1300 cal yr BP on the southern slope, when chironomid-inferred summer temperatures increased and the pollen record documents increased anthropogenic activity near the treeline. However, the forest clearance by burning to increase grazing land was subdued in comparison to other European regions.

Keywords

Fire history; Treeline; Holocene; Carpathians; Plant macrofossils

1. Introduction

Understanding the factors that influence the natural variability of disturbance regimes is important for ecosystem conservation and restoration purposes. In European mountain regions, fire is increasingly acknowledged as a natural agent of disturbance. However, the higher disturbance frequency predicted for the next century in high-elevation ecosystems (Wastl et al., 2012) may pose new challenges to fire management in Europe (Valese et al., 2014). Two main factors make fire an increasingly relevant ecological factor in European mountain ecosystems. Timberlines (i.e. the line delimiting closed forests) that were shifted downslope by the creation of summer pastures and meadows for intensified grazing activities (Baur et al., 2007; Tinner, 2007) are predicted to shift upwards again due to abandonment of agricultural practices in economically marginal areas and the effects of climate warming on the treeline ecotone (Gehrig-Fasel et al., 2007; Schwörer et al., 2014). The resulting higher forest connectivity and biomass availability (fuel) in the future treeline ecotone will facilitate the spread of fires. Secondly, the potentially higher frequency of exceptional droughts due to climate change in some areas (e.g. Southern and Central Europe) (Schär et al., 2004) may increase the frequency of favourable weather conditions for fire ignition and spread.

Vegetation responses to environmental changes are extremely complex, and this complexity may be more striking due to interactions between vegetation composition and environmental conditions such as climate and fire-disturbance regimes (Gavin et al., 2006; Higuera et al., 2009). Although climatic factors are generally considered to be the predominant driver of fire regimes (Daniau et al., 2012), vegetation composition and woodland cover can modulate the effects of climate by controlling the type and structure of fuel available for combustion (Higuera et al., 2009; Gil-Romera et al., 2014). Palaeoecological records allow short-term instrumental and documentary records to be extended back over several millennia and make it possible to investigate the natural variability of fire regimes, the human dimension of fire

regimes (Bowman et al., 2011), and vegetation-fire interactions, through the analysis of pollen, plant macrofossils, and charcoal particles stored in sedimentary archives (Stähli et al., 2006; Morales-Molino et al., 2015).

The Retezat Mountains (Southern Carpathians, Fig. 1) are an interesting area to investigate long-term vegetation-fire-climate interactions. Forest fires are not widespread in the Romanian Carpathians and are considered as a negligible cause of ecosystem disturbances today (Knorn et al., 2013). In keeping with this, previous charcoal records from a high-elevation site in the Southern Carpathians (Lake Brazi: Feurdean et al., 2012; Finsinger et al., 2014), showed that fires were frequent during the drier early Holocene, and that fire activity was less during recent millennia when humans were potentially clearing the treeline ecotone. This temporal pattern of charcoal records markedly contrasts with the strong biomass-burning increase recorded in the Alps at the Neolithic/Bronze Age transition (about 4000 cal yr BP in the Alpine region), when humans cleared the forest to create summer pastures and meadows and effectively shifted the fire regime outside its natural range of variability (Valese et al., 2014). It also contrasts with charcoal records from the lowland Transylvanian plain where fire frequency markedly increased at about 3000 cal yr BP (Feurdean et al., 2013a). Long-term charcoal records show that fire occurrence can be highly variable both spatially and temporally and that fires are less likely to occur and to spread on more humid northern exposures due to the control of local climatic factors on fuel load and flammability (Whitlock and Larsen, 2001; Carcaillet et al., 2009; Barrett et al., 2013). The Lake Brazi record is located on the northern slope of the range. Hence, it may only be reflecting local fire occurrences on the less fire-prone northern slope of the mountain range.

Therefore, we chose a contrasting site on the southern slope to provide temporal and spatial estimates of past fire-regime variability in the Southern Carpathian treeline ecotone. We present two well-dated multi-proxy (continuous records of macroscopic charcoal, pollen,

stomata, and plant-macrofossils) reconstructions of vegetation and fire history from the Retezat Mountains, covering the past 11,000 years to determine the relationship between local fire regimes and vegetation changes at the treeline ecotone (see also Magyari, Orbán et al., in this issue; and Vincze et al., submitted for publication). We use the macroscopic charcoal record (i) to identify fire episodes and to infer fire-return intervals (FRI, i.e. the time elapsed between two successive fire episodes) using peak-detection analysis (Lynch et al., 2003; Higuera et al., 2009; Finsinger et al., 2014), and (ii) to reconstruct longer-term variations in biomass burning by means of total macrocharcoal accumulation rates (CHAR) that may reflect an integrated signal of charcoal production (depending on burnt area, amount of biomass burnt, and fuel load availability), fire frequency, and deposition and taphonomic processes such as reworking and sediment focusing (Whitlock and Larsen, 2001; Kelly et al., 2013). Because variations in total CHAR depend on the sediment-accumulation rates, we devised a new numerical method to test the influence of modelled sedimentation rates in determining long-term variations of total CHAR. These vegetation and fire proxies, together with a suite of regional climate proxies (Buczkó et al., 2013), including a chironomid-based July-air temperature reconstruction from Lake Brazi (Tóth et al., 2015), enable us to examine vegetation–fire disturbance–climate interactions.

2. Material and methods

2.1. Study area

Due to its inland position, the climate of the Carpathian Mountains arc is classified as temperate-continental. The Retezat Mountains (Romania), being located at the western edge of the strongly dissected southern part of the Carpathian arc, stand out as one of the wettest massifs of the arc, with annual precipitation ranging between 900 and 1800 mm. Mean annual

temperature is around +6 °C in the foothill zone and -2 °C at 2500 m asl (Bogdan, 2008) and the main wind direction is from W-WNW (Mîndrescu et al., 2010). The vegetation in the Retezat Mountains is dominated by *Fagus sylvatica* forests in the montane belt (around 800–1200masl) that are followed up to about 1400masl by mixed forests mainly composed of *F. sylvatica*, *Abies alba*, and *Picea abies*. These are replaced upslope by a mosaic of conifer forests dominated by *P. abies* intermixed with *Pinus cembra* (particularly above 1750 m asl) and *Pinus mugo* shrublands on exposed cliffs and mires up to the timberline, which is located around 1850–1900masl. The treeline, located around 1950–2000 m asl, is formed by isolated *P. abies* and *P. cembra* trees. Above the treeline, subalpine shrublands, with *P. mugo*, *Vaccinium myrtillus*, and *Juniperus communis* give way to alpine meadows. *P. mugo* and *Juniperus* are often dominant between 2000 and 2200 m asl (Borza, 1934; Nyárády, 1958; Csűrös, 1971).

2.2. Study sites

Lake Brazi (Tăul dintre Brazi: 45°23'47" N; 22°54'06" E) is a small shallow lake (about 0.4 ha; maximum water depth: 1.1 m) located at 1740 m asl in the Gales, ului valley, at the north-eastern edge of the Retezat National Park (Fig. 1). It has no inflowing stream and is located about 110m below the present timberline in a mixed conifer forest dominated by *P. abies* and *P. cembra*. The lakeshore is covered by a floating Sphagnum moss carpet on which dwarf pine (*P. mugo*) shrubs are abundant (Magyari et al., 2012).

Lake Lia (Lacul Lia: 45°21'7.2" N; 22°52'36.3" E) is a slightly larger and deeper lake (1.26 ha; maximum water depth: 4.2 m) located at 1910 m asl in the Bucura valley, on the southern slope of the Retezat Mountains (Fig. 1). The lake receives water from two inflow streams, one of them being the outflow of Lake Bucura (2040 m asl). Lake Lia is just below the

current treeline (1930 m asl) and is surrounded by dense *P. mugo* thickets on the steep rocky western slope and by grazed meadows on its flatter northern shore. The nearest isolated *P. abies* trees grow about 100–150 m away and one small sapling 50 cm high grows on the northern shore. However, in nearby valleys on the southern slope of the Retezat Mountains solitary trees may be found up to about 2000 m asl.

2.3. Coring and chronology

Sediment cores from Lake Brazi (6.6 m long) and Lake Lia (8.8 m long) were retrieved using a modified Livingstone piston corer (Walker, 1964) operated from a raft in 2007 and 2008, respectively. The topmost 30 cm of unconsolidated sediment from the Lake Lia could not be retained and were therefore not sampled.

The age–depth relationships for the Holocene sediments of Lake Brazi and Lake Lia were modelled using 21 and 16 ^{14}C dates on terrestrial plant macrofossils and on the organic sediment fraction (mostly <250 mm), respectively (for Lake Brazi see Finsinger et al., 2014; for Lake Lia see Hubay et al., in this issue). To fit an age–depth model we used the smooth spline fitting function in CLAM v2.1 (Blaauw, 2010). The two age–depth models were not extrapolated beyond the lowest ^{14}C dates for the core sections that were analysed in this study. They gave sediment-deposition times less than 40 years cm^{-1} except in the oldest part of the Lake Brazi sequence (11,260–11,000 cal. BP). This warranted the interpolation of the macro-CHAR record to a temporal resolution of 40 years prior to further numerical analyses (see next sections).

2.4. Loss-on-ignition

Sediment samples of ca. 1 cm³ were dried at 105 °C for 24 h and dry sediment samples (ca. 1–1.5 g) were ignited at 550 °C for 4 h. Percentage loss-on-ignition (LOI) was calculated following Heiri et al. (2001).

2.5. Plant-macrofossil, stomata, and pollen analyses

Sediment subsamples (on average 9 cm³) of Lake Brazi were briefly soaked in 10% NaOH and wet-sieved through 250 µm and 180 µm meshes. Lake Lia sediment subsamples (on average 20 cm³) were soaked in dilute Na₄P₂O₇ if necessary to disaggregate the sediment (high silt content) and sieved through 125-µm mesh. Identifications and counts were made under a stereomicroscope at x 10–40 magnification with the aid of identification keys and by comparison with reference material. Plant-macrofossil accumulation rates (number cm⁻² yr⁻¹) were obtained by dividing concentration values (number cm⁻³) by the sediment-deposition times (yr cm⁻¹) (Bennett and Willis, 2001). The concentrations of plant macrofossil parts identified at taxon level were summed together to estimate population-size changes for *P. mugo*, *Picea*, *Juniperus*, *P. cembra*, and Pinaceae as follows: *P. mugo* = Σ(needles + male cone with anthers + anthers + seeds + seed wings); *P. cembra* = Σ (needles + anthers + seeds); *Picea abies* = Σ(needles + twigs + anthers + seeds + seed wings + female cone scales + male cone scales); *Juniperus* = Σ(needles + twigs); Pinaceae = Σ(seeds + seedwings + female conescales + bud scales + indet. needles + indet. anthers + indet. twigs).

One cm³ sediment subsamples were prepared for pollen analysis in the laboratory using standard methods (Bennett and Willis, 2001), but excluding the acetolysis step. Pollen, spores, and stomata were identified and counted at 400x and 1000x magnification. Pollen was identified with the help of atlases (Reille, 1995, 1992) and identification keys (Moore et al., 1998; Beug, 2004). Pollen percentages were calculated based upon the total sum of terrestrial

pollen grains (>500 for each sample). Stomata were identified and counted on pollen slides (Trautmann, 1953; Sweeney, 2004; Magyari et al., 2012).

In order to detect vegetation changes associated with the creation of pastures, meadows and trampled ground around the study sites, percentages of secondary anthropogenic pollen indicators associated with those habitats (e.g. *Plantago lanceolata* and *Plantago major/media*) were summed, following Vincze et al. (submitted for publication).

Plant-macrofossil and stomata records are useful proxies to reconstruct local vegetation changes at the treeline ecotone in Central and South-eastern Europe (Birks and Birks, 2000; Magyari et al., 2012; Ammann et al., 2014) where conifers and Ericaceae form the main tree and shrub cover. Pollen transported from lower forested elevations into alpine vegetation with low local pollen productivity blurs the pollen records. Nevertheless, pollen percentages are shown in the figures, because plant-macrofossils and pollen are complementary proxies for vegetation change (Finsinger and Tinner, 2007; Jackson et al., 2014).

2.6. Charcoal analyses

We used microscopic charcoal influx as a proxy for regional fire activity and regarded the occurrence of macroscopic charcoal particles as evidence of local fire activity (Whitlock and Larsen, 2001; Conedera et al., 2009). Microcharcoal particles (>10 μm in diameter) were counted on pollen slides with added Lycopodium tablets of known concentration (Stockmarr, 1971) under a transmitted-light microscope following Tinner and Hu (2003) and Finsinger and Tinner (2005). Counts were transformed to influx values ($\text{number cm}^{-2} \text{ yr}^{-1}$).

For macrocharcoal analysis, contiguous 1 cm^3 subsamples were taken from the upper 550 cm and 440 cm of the Lake Lia and Lake Brazi sediment cores, respectively. Subsamples were deflocculated and bleached using NaOH (10%) and NaOCl (2%), and gently sieved through a

160 μm mesh under a soft water jet (Genries et al., 2012). The residue was carefully washed into a porcelain evaporating-dish to aid identification and counting of charcoal particles against the white background. The material was analysed at x60 magnification under a Leica M80 binocular microscope equipped with a video camera that was connected to an image analyser fitted with Winseedle image-analysis software (Regent Instruments Canada Inc., 2009) that allowed the measurement of total charcoal concentration by number, charcoal areas of individual particles, and the cumulative sum of charcoal-particle areas (i.e. the concentration of charcoal by area).

2.7. Fire-episode reconstructions

For fire-episode reconstructions, macroscopic charcoal concentrations by number and by area were transformed to charcoal-number and charcoal-area accumulation rates (here denoted CHARC: number $\text{cm}^{-2} \text{yr}^{-1}$ and CHARA: $\text{mm}^2 \text{cm}^{-2} \text{yr}^{-1}$, respectively) by dividing the concentrations with the estimated sample-deposition time (yr cm^{-1}) as inferred from the age-depth models. The CHARC and CHARA records were used to infer local fire episodes in two different CharAnalysis runs (following Finsinger et al., 2014). The records were first interpolated to a constant temporal resolution of 40 years (CHAR_i) and then broken down into a low-frequency background component ($\text{CHAR}_{\text{back}}$) and a peak component ($\text{CHAR}_{\text{peak}}$) using a robust locally weighted polynomial regression (LOWESS) with a moving-window width of 900 years. This resulted in a robust signal-to-noise index (SNI) (Kelly et al., 2011) and goodness-of-fit between the empirical data and the $\text{CHAR}_{\text{back}}$ data for both the count- and area-based records. The $\text{CHAR}_{\text{peak}}$ component was evaluated with a Gaussian mixture model that aimed at separating peak samples representing actual fire events from surrounding noise in the $\text{CHAR}_{\text{peak}}$ series. For each 900-yr window, $\text{CHAR}_{\text{peak}}$ values exceeding the 99th percentile threshold of the modelled noise distribution were identified as potential fire

episodes (Higuera et al., 2009). Thereafter, identified charcoal-count-based fire peaks were screened with the minimum-count peak-screening test (Gavin et al., 2006; Higuera et al., 2010) and charcoal-area-based peaks were screened with the method proposed by Finsinger et al. (2014). For peak-detection, peak-screening analyses, and local-fire episode reconstructions we used CharAnalysis v1.1 (Higuera et al., 2009) and ARCO v1.0 (Finsinger et al., 2014).

2.8. Change point analyses

To investigate the long-term variations of local biomass burning, we determined the locations of change points (Killick et al., 2012) based on variations of the mean and variance in the CHAR records using the binary segmentation method (Scott and Knott, 1974) in the ‘changepoint’ v1.1.5 package (R Core Development Team, 2012; Killick et al., 2014), following Rius et al. (2014). The binary segmentation is an iterative search method that tests if a change point at position t exists that, at each iteration, separates an ordered sequence of data ($y_{1:n} = (y_1, \dots, y_n)$) into two segments ($y_{1:t} = (y_1, \dots, y_t)$, $y_{t+1:n} = (y_{t+1}, \dots, y_n)$). At each iteration a change point is retained if a cost function applied to the entire sequence ($\Omega_{1:n}$) is larger than the sum of the cost functions applied separately to the two segments plus a penalty β to guard against overfitting ($\Omega_{1:t} + \Omega_{t+1:n} + \beta$), until no change points that meet this condition are detected (Killick et al., 2012). Here we selected a user-defined penalty ($\beta = 4 \log(n)$), following Killick et al. (2012). The change-point analysis has some analogy with the sequence-splitting technique (Birks and Gordon, 1985; Birks and Line, 1994).

Because variations in total CHAR may also arise due to variations in estimated sedimentation rates, we devised a new method to test the influence of modelled sedimentation rates in determining long-term variations of total CHAR. The method starts by generating a user-

selected number (here 1000) of random charcoal-concentration records with values ranging between the minimum and maximum value of the charcoal record being analysed. For each randomly generated record, concentrations are then transformed to CHAR using (i) a constant sedimentation rate ($\text{CHAR}_{\text{rand}}$) and (ii) the sedimentation rate from the age-depth model ($\text{CHAR}_{\text{sedrate}}$), and both records are then analysed to determine the locations of change points. In theory, no change points should be detected in the $\text{CHAR}_{\text{rand}}$ series. However, because change points can arise by chance in the randomly generated $\text{CHAR}_{\text{rand}}$ time series, the method retains only those change points that are detected in more than 2.5% of the 1000 runs, effectively screening out the chance change points. Visual inspection of the location of change points in the CHAR records and in the $\text{CHAR}_{\text{sedrate}}$ series may thus reveal the occurrence of change points that are likely to arise from variations in sedimentation rates rather than from changing charcoal abundances alone. The R script is available from the authors on request.

3. Results and interpretation

3.1. Fire-history reconstruction

Macroscopic charcoal concentrations ranged between 0 and 10 pieces cm^{-3} in most of the samples from both sequences (Fig. 2). At Lake Brazí, CHAR_A and CHAR_C values were highest in two periods centred on 10,800 and 9200 cal yr BP, then gradually decreased to reach lowest values around 6000 cal yr BP, and thereafter slightly increased to reach a local maximum at 500 cal yr BP (Fig. 3). At Lake Lia, in contrast, CHAR_A and CHAR_C values were highest in three distinct periods: 9000–7500 cal yr BP, 5500–4500 cal yr BP, and 750–250 cal yr BP (Fig. 3). Generally, macroscopic charcoal concentrations, micro-CHAR, macro- CHAR_C and macro- CHAR_A records show similar trends, although in some cases with

different amplitudes (Fig. S1). This is most noticeable in Lake Lia, where macro-CHAR_A drops more rapidly at 7800 cal yr BP than macro-CHAR_C, and between 750 and 250 cal yr BP, where macro-CHAR_C and micro-CHAR values rise more steeply than macro-CHAR_A values.

Based on the peak-detection analysis of the CHAR_A and CHAR_C datasets at Lake Brazí (Fig. 2), 7 and 8 distinct fire episodes occurred during the past 11,500 years, respectively. FRIs (Fig. 4a) were lowest (<240 years) at about 8400–8150 cal yr BP and otherwise ranged between 1000 and 4000 years (for more details on Lake Brazí's fire-episode reconstruction see Finsinger et al., 2014). At the south-exposed Lake Lia, 7 and 17 fire episodes were identified based on the CHAR_C and CHAR_A datasets, respectively (Fig. 3). The signal-to-noise ratio (SNI) of the CHAR_C record (Fig. S2) ranged between 2.8 and 9 (median = 3.7) and was smaller than 3.0 between 9000 and 6000 cal yr BP, indicating that it is not suitable for peak-detection analysis (Kelly et al., 2011). The SNI of the CHAR_A record (Fig. S2) ranged between 2 and 9 (median = 5.7) and was lower than the critical threshold (3.0) only in the most recent part of the record (<500 yr cal BP). FRIs based on CHAR_A ranged between 80 and 1650 years, with shortest FRIs (mostly <500 years) clustering in three periods: 8450–7050, 5300–4500, and 1900–1300 cal yr BP (Fig. 4b).

Change points in the randomly generated CHAR_{sedrate} series clustered in locations where sediment-accumulation rates rapidly changed (Fig. 3). The change-point analysis for Lake Brazí indicates that total CHAR_C changed at about 9200 and 7100 cal yr BP. However, the latter change point coincides with change points that occurred also in the randomly generated CHAR record, suggesting that it might have also occurred due to variations of the sediment-accumulation rate. Conversely, the analysis failed to detect change points between the two local maxima centred around 10,800 and 9200 cal yr BP. Nine change points, in contrast, split the CHAR_A record. Two of them were determined by variations of single (or few)

samples and are therefore not retained further. The CHAR_A record can be thus subdivided into three phases, with two phases (11,500–8100 and 4700–250 cal yr BP) being characterized by higher values. None of the change points detected in the CHAR_A record coincided with change points in the randomly generated series. The first period (11,500–8100 cal yr BP) may be further subdivided into four zones, two of which (centred around 10,800 and 9200 cal yr BP) are characterized by higher means.

The change-point analysis for the Lake Lia CHAR_A records indicates a distinct period marked by higher values (8900–6900 cal yr BP) (Fig. 3). The analysis shows two additional periods with higher CHAR_A mean and variance (5500–4500 and 2800–250 cal yr BP). Even if the onset of the higher-biomass burning period around 2800 cal yr BP is unsure because the change-point analysis was possibly influenced by the occurrence of one sample having a higher CHAR_A value (at 2700 cal yr BP), CHAR_A values were slightly higher after 2000 cal yr BP than between 4500 and 2000 cal yr BP. The rapid CHAR rise at 450 cal yr BP is probably not significant because it coincides with change points that were detected also in the randomly generated CHAR records.

The user-determined penalty value b is largely arbitrary and can greatly influence the results of the change-point analysis (Killick et al., 2012): increasing (decreasing) the penalty value decreases (increases) the number identified segments. This issue is analogous to defining the number of zone boundaries in a multivariate dataset, say a pollen record (Grimm, 1987; Bennett, 1996). However, the change-point analysis was not used to determine how many change points could be detected within a record but rather to compare the locations of change points in the CHAR and in the randomly generated $\text{CHAR}_{\text{sedrate}}$ records based on the same penalty values. The method effectively suggests that the rapid CHAR increase at 450 cal yr BP in the Lake Lia record is likely influenced by variations in sediment-accumulation rates,

which are related to intensified soil erosion as shown by lower loss-on-ignition values (Fig. 4).

Several peaks initially identified as fire peaks were screened out because they were deemed to be potentially unreliable (Higuera et al., 2010; Finsinger et al., 2014). While the flagged peaks may be related to insignificant variations in the charcoal-abundance estimates, they may also be caused by the occurrence of distant fires (Higuera et al., 2010; Oris et al., 2014) or low-intensity/small area-burnt fires. Modern fire sizes in the Southern Carpathians are small (<750 ha; European Forest Fire Information System (EFFIS)) compared to naturally occurring wildfires in boreal forests that usually burn areas >10,000 ha (Kasischke et al., 2002). Hence, we can expect that several small-area fires were not retained as significant fire episodes with the peak-identification analysis. Regardless, periods of higher biomass burning as revealed by the change-point analysis of the total CHAR record and by low-frequency variations of CHAR_{back} records (Figs. 3 and 5) broadly coincide with periods of shorter FRIs, in agreement with the notion that variations in total CHAR can also be influenced by variations of fire-episode frequency (Kelly et al., 2013). Because the pattern is particularly distinct in area-based CHAR_A records (Fig. 5), the shorter dispersal distances of larger charcoal particles (Clark, 1988; Oris et al., 2014) may be one reason explaining the more distinct variations in those records than in the count-based CHAR_C records.

3.2. Fire-vegetation relationships

As attested by the abundant plant macrofossils in Lake Brazi (Fig. 4a), the north-exposed lake was always below the timberline for the past 11,000 years. Until about 10,200 cal yr BP, light-demanding pioneer species (*Larix*, *Betula*, and *P. mugo*) were present around the lake together with *P. abies* and shrubs (*Vaccinium*). High CHAR and CHAR_{back} values attest to

high biomass burning at that time. Thereafter, *Larix*, *Betula*, and *Vaccinium* disappeared locally and *P. abies* and *P. mugo* became dominant with scattered *P. cembra* until about 4500 cal yr BP. *P. mugo* probably grew locally on the floating bog that developed on the lakeshores, as it does today (Magyari et al., 2011). Under lowest biomass burning conditions (between 8000 and 4500 cal yr BP) local vegetation was dominated by *P. abies*. Biomass burning moderately increased around 4500 cal yr BP, synchronous with the local expansion of *P. cembra* and a very small increase in herb pollen percentages. Rising abundances of anthropogenic-pollen indicators suggest that human activities first modified the landscape near Lake Brazi around 3000 cal yr BP and resumed about 1500 cal yr BP onwards (Fig. 4a). The CHAR record shows that human activities did not substantially alter the fire regime in comparison to the mid-Holocene. However, peaks of anthropogenic pollen indicators coincide with phases of moderately higher biomass burning and with fire-episodes at about 3000 cal yr BP and starting from ~1500 cal yr BP, suggesting that human activities were associated with the use of fire.

Lake Lia was located in the treeline ecotone until about 8000 cal yr BP as attested by the concentrations of *P. mugo* and *P. abies* macrofossils and the high abundance of *Vaccinium* and herbaceous plant macrofossils (Fig. 4b). The stomata record from Lake Lia also supports this interpretation. The high abundance of herbaceous macrofossils until 8000 cal yr BP reflects the large extent of wet habitats. At Lake Lia, *P. mugo* probably grew on the lakeshore, particularly on the western steep rocky slope. Increasing abundance of *P. abies* macrofossils, however, indicate that the timberline was gradually creeping up the slope. Between 9000 and 8000 cal yr BP the density of the forest increased at Lake Lia and the lake remained below the timberline until about 3000 cal yr BP (Orbán et al. this issue). Between 5800 and 3000 cal yr BP, *P. abies* was co-dominant with *P. cembra*. Fire activity increased (lower FRIs and higher biomass burning) between 5800 and 4500 cal yr BP. CHAR values

remained overall low between 4500 and 2800 cal yr BP. After about 3000 cal yr BP, loss of tree macrofossils and low values of *P. mugo* macrofossils suggest that the treeline moved downhill and Lake Lia was situated mainly in the krummholz zone, as also suggested for other sites in the Retezat Mountains (Fărcas, et al., 1999). Decreasing LOI 550 °C values indicate that soil erosion increased between 4000 and 3000 cal yr BP, when the timberline descended. Short-term increases of CHAR values and robust charcoal peaks allow the identification of local-fire episodes during the past 2800 cal yr BP, i.e. after the soil-erosion increase. Anthropogenic-pollen indicators suggest that human activities modified the vegetation from 2200 cal yr BP onwards around Lake Lia. Concomitantly, FRIs decreased suggesting that some fire episodes were linked to human activities.

4. Discussion

4.1. Spatial differentiation

At the treeline ecotone, site history, including climatic changes, wildfire history, and past human impact, play important roles in determining the current sensitivity of the climatic treeline to changing climate (Holtmeier and Broll, 2005). Reconstructed fire regimes on the two opposite slopes of the Southern Carpathians were markedly different (Fig. 5): the number of inferred fire episodes was smaller on the northern than on the southern slope, where periods of higher biomass burning and of more frequent fire episodes (shorter FRIs) occurred during the mid to late Holocene (Fig. 2). In theory, the small distance between the two sites (5 km, Fig.1) does not preclude transport of charcoal particles between the two mountain slopes (Pisaric, 2002; Tinner et al., 2006; Oris et al., 2014). However, the different fire histories of the two sites can be more economically explained by the assumption that the mountain ridge (about 2300 m asl) acted as an efficient barrier to charcoal transport between

the mountain slopes. The situation is similar to that of today, where the southern slope is more fire prone: over the past 10 years fires were smaller and less frequent on the northern than on the southern slopes (mostly no fires or burnt areas $<100 \text{ ha yr}^{-1}$ against more frequent fires and burnt areas reaching 750 ha yr^{-1} , respectively (European Forest Fire Information System (EFFIS)). Contrasting spatial patterns of fire regimes have also been reconstructed based on macrocharcoal records elsewhere (Whitlock and Larsen, 2001; Carcaillet et al., 2009; Genries et al., 2012) and highlight the need to increase the spatial density of palaeo-records to reconstruct region-specific spatial patterns of fire-regime changes. The results are therefore consistent with observations that trends and patterns of change can be different for sites situated close to each other (Gavin et al., 2006; Feurdean et al., 2012).

4.2. Drivers of the fire regime

Biomass burning at Lake Brazi and Lake Lia was highest during the early Holocene (Fig. 5) probably because of drier climatic conditions linked to stronger summer insolation, as elsewhere in the Carpathians (Feurdean et al., 2012). The chironomid-inferred July air temperatures (CI-T) record at Lake Brazi (Tóth et al., 2015) closely follows summer insolation changes during the Holocene remaining mostly above present-day temperatures until about 6000 cal yr BP. However, the timing of the early-Holocene biomass-burning maximum was different at Lake Brazi and Lake Lia. Whereas CHAR strongly decreased at Lake Brazi ca. 9200 cal yr BP, at Lake Lia CHAR strongly increased at this time, suggesting that local factors may have been important in driving fire-regime changes. Early spring and growing-season climatic conditions exert a primary control on fire regimes due to their effects on fire ignition and spread and on fuel availability (Körner and Paulsen, 2004; Schwörer et al., 2014). Similar conditions have been inferred in other palaeoecological records around the treeline ecotone (Gil-Romera et al., 2014).

4.3. Fire history and vegetation changes at Lake Lia and Lake Brazí

The treeline ecotone persisted longer at Lake Lia than at Lake Brazí (until about 8000 cal yr BP) during the early Holocene because Lake Lia is located about 160 m higher, which might result in a mean monthly temperature difference of $\sim 1\text{--}1.5\text{ }^{\circ}\text{C}$ using a thermal lapse rate of $\sim 0.6\text{ }^{\circ}\text{C}/100\text{ m}$ elevation (Agustí-Panareda and Thompson, 2002) between the two lakes. The lower temperatures at Lake Lia might have advantaged *Pinus mugo* and Ericaceous shrubs, which are more tolerant against thicker and longer-lasting snow cover than *P. abies* (Holtmeier, 2009). The rocky surface of a rock glacier on the western shore of Lake Lia (Urdea, 1992) may also have hindered the establishment of *P. abies*, which requires thicker soils (Henne et al., 2011). In addition, lingering permafrost in the rock glacier after the end of the Younger Dryas may have lowered the local ground temperature (Vespremeanu-Stroe et al., 2012).

However, *P. abies*, *P. cembra* and Pinaceae macrofossils were already found from about 10,500 cal yr BP at Lake Lia (Fig. 4), indicating that the treeline ecotone was approaching and that individual trees grew near the lake for about 2000 years before the timberline ascended above it (see also Orbán et al. this issue). Moreover, CI-T (Fig. 5) reached their highest values around 9400 cal yr BP, shortly before the onset of the first high-biomass burning and short FRIs period, and shortly before woody biomass locally increased as suggested by variations of *P. abies* macrofossil abundances. Taken together, this evidence suggests that frequent fires in the treeline ecotone between 9000 and 8000 cal yr BP could have prevented the closure of the timberline forest and helped to maintain a rather open landscape with abundant herbs and Ericaceae in the treeline ecotone until 8000 cal yr BP, when the *P. abies* dominated timberline finally ascended above the lake. Higher biomass burning and shorter FRIs starting from about

9200 cal yr BP also coincide with low lake levels at Lake Brazi and at other sites in the Carpathians from around 9000 cal yr BP (Buczkó et al., 2013) suggesting that the climate became relatively dry. Hence, biomass burning before 9000 cal yr BP at Lake Lia may have been low due to the combination of low fuel availability that limited local fire occurrence and moist local climatic conditions. In contrast, the reduced local fire activity around Lake Brazi was probably due to the modulating effect of the dominance of *P. abies* throughout the Holocene, a species observed to reduce fire activity (Ohlson et al., 2011; Schwörer et al., 2015), and possibly more humid conditions on the northern slope.

Fire activity at Lake Lia remained high until about 7000 cal yr BP probably because fuel availability increased, as attested by the lower abundance of herbaceous macrofossils and increased abundance of *P. mugo* and *P. abies* plant macrofossils. High percentages of *Corylus* pollen, transported from lower elevations, were recorded until about 7400 cal yr BP (Vincze et al., submitted for publication). *Corylus* is a fire-resistant resprouter (Finsinger et al., 2006) and may suggest that climatic conditions were still sufficiently dry to support high biomass burning in the *P. abies* dominated timberline forest. Dry climate conditions until about 7000 cal yr BP are also indicated by higher-than present CI-T (Fig. 5) and by low lake-levels at Lake Brazi (Buczkó et al., 2013).

Between ca. 7100–6900 cal yr BP, CI-T decreased in a step-like manner (Fig. 5). Decreasing summer temperatures can well explain the rapid timberline-species descent at 6000–5000 cal yr BP, marked by the local expansion of *P. cembra* at Lake Lia and later at Lake Brazi. The cooling may have reduced evapotranspiration, thus also reducing fire occurrence at Lake Lia. The later expansion of *P. cembra* at Lake Brazi could be explained by the lower elevation of Lake Brazi where the zone of *P. cembra* occurrence would arrive later as the treeline descended, and the competition provided by the closed *P. abies*-dominated forests below the

timberline on the northern slope that were less affected by the summer temperature change after 7000 cal yr BP.

Surprisingly, biomass burning increased and FRIs became shorter at Lake Lia between 5500 and 4500 cal yr BP, when CI-T were lower (Fig. 5) and diatoms suggest higher lake levels and/or increasing water turbulence at Lake Brazi (Buczkó et al., 2013) than previously. Similarly, increasing lake levels and cooler climate conditions, which do not comply with increased fire occurrence, were noted from the Eastern, the Western and from other parts of the Southern Carpathians between 5500 and 4200 cal yr BP (Tóth et al., 2015). An interval characterized by higher charcoal abundance is also visible in other records from the Carpathians located between 1000 and 1400 m asl between 5800 and 4800 cal yr BP (Feurdean et al., 2012). In those records the charcoal abundance increase coincides with the pollen-inferred rapid expansion of *Carpinus betulus* that may have been favoured by a higher fire activity in the montane belt (Feurdean et al., 2012). However, the biomass-burning increase at Lake Lia was not related to the expansion of *C. betulus* at lower elevation because the rise of *C. betulus* pollen percentages already started ca. 1000 years earlier (Vincze et al., submitted for publication). We cannot exclude that charcoal particles were transported from burnt areas located at lower altitudes, as may happen in areas with steep topography (Tinner et al., 2006). Neither archaeological data nor anthropogenic indicators (*Cerealia*, *Secale*, or secondary indicators) suggest early livestock grazing during the late Neolithic in the Retezat Mountains (Fig. 4 and Vincze et al., submitted for publication), in contrast to the northern Romanian Carpathians (Feurdean et al., 2016).

4.4. Did anthropogenic fires influence the late-Holocene treeline ecotone vegetation?

The absence of evidence for early human activities and decreasing CI-T around 3000 cal yr BP suggest that decreasing summer temperature caused a downslope timberline shift at Lake Lia. In spite of reduced fuel-availability due to the subsequent dominance of *P. mugo* shrublands at Lake Lia, fires still occurred. A comparison between Lake Lia's fire record and climate proxies suggests that climatic conditions possibly continued to influence the fire regime: the short-FRI period between 1900 and 1300 cal yr BP at Lake Lia matches well with a period characterized by increasing CI-T (Fig. 5) and by the gradual shallowing and eutrophication of Lake Brazi (Buczkó et al., 2013); likewise, higher lake level at Lake Brazi between 3010 and 2800 cal yr BP coincides with decreased fire activity. Yet, the CI-T and the diatom-inferred water-depth reconstructions may be influenced by anthropogenic nutrient enrichment, casting doubt on the climate–fire relationship.

Fires can have a significant and long-lasting impact on vegetation structure and composition by disfavouring fire-sensitive species and by promoting open spaces and fire-resistant species (Stähli et al., 2006; Leys et al., 2014b; Schwörer et al., 2015). Short FRIs, ranging between 80 and 560 years fire⁻¹, occurred between 1900 and 1300 cal yr BP at Lake Lia. The increase of secondary anthropogenic-pollen indicators (mainly *P. lanceolata*) from ca. 2000 cal yr BP at Lake Lia (Fig. 4) suggests that anthropogenic disturbance could also have contributed to the increase in fire activity through intentional burning of the *P. mugo* shrublands to open the landscape further for summer pastures and meadows. These short FRI estimates are in broad agreement with records from the Alps, where *P. mugo* has been observed to be resistant to, and possibly even favoured by, the occurrence of fires with FRIs of ca. 250 years (Stähli et al., 2006) and 30e735 years fire⁻¹ (Leys et al., 2014a). Such low FRIs also comply with the qualitative assessment of the flammability of *P. mugo*, which was rated as “producing fires that likely present significant control problems requiring effort and resources” (Xanthopoulous et al., 2012).

Warming climate, as shown by increasing CI-T (Fig. 5), might have favoured high-altitude pastoral activities as also suggested for the Rodna Mountains (Geanta et al., 2014), Apuseni Mountains (Feurdean et al., 2009) and the Alps (Tinner et al., 2003). Human activities (pastoralism, clearance, burning) may have prevented the timberline from rising naturally in the warmer conditions. The rapid increase of anthropogenic-pollen indicators together with decreasing pollen abundances of *P. mugo* and *P. cembra* around 700 cal yr BP at Lake Lia suggests that the local tree and shrub cover was opened by more intensive pastoral activity during the Middle Ages, when anthropogenic land-cover change involved greater clearance of the mountain-pine thickets to obtain new pastures (Solár and Janiga, 2013). The absence of detected fire-episodes from 700 cal yr BP onwards at Lake Lia may thus be the result of reduced fuels due to livestock grazing that effectively suppressed fire occurrence (Bowman et al., 2011) by thinning the *P. mugo* shrublands for grassland. At Lake Brazi, in contrast, discontinuous occurrence of anthropogenic-indicator pollen (Fig. 4) since 2600 cal yr BP suggests that human activities were less extensive in the *P. abies* dominated forest below the timberline than on the southern slope. Nevertheless, distinct anthropogenic-indicator pollen peaks coincide with charcoal peaks (some of which were identified as fire episodes) supporting the notion that pulses of anthropogenic land-cover change alternated with rapid forest regeneration (Tinner et al., 2003; Finsinger and Tinner, 2006; Feurdean et al., 2013b).

4.5. Comparison with other central European regions

The fire history in the Southern Carpathian treeline ecotone differs from the lowland Transylvanian plain and elsewhere in Europe, where a distinct shift from natural to “human fire regimes” has been detected at the Neolithic/Bronze Age transition (Tinner et al., 1999; Feurdean et al., 2012; Molinari et al., 2013; Morales-Molino and García-Antón, 2014). In those regions, late-Holocene biomass burning, as inferred from CHAR records and from FRI

reconstructions, markedly exceeded the mid-Holocene range of variability, often leading to substantial changes in vegetation composition and sometimes to the local extinction of fire-sensitive species (Tinner et al., 2000; Rey et al., 2013; Morales-Molino et al., 2015). The comparatively low late-Holocene fire activity (Fig. 5) and the late appearance of anthropogenic-pollen indicators in the Retezat Mountains suggest that prehistoric cultures exploited the marginal high-mountain pastures less intensively than in the Alps.

Since the Middle Ages, more intensive land-use of subalpine pastures led to a drastic thinning and/or reduction of *P. mugo* thickets throughout the Carpathians (Nedelea and Comănescu, 2009), thereby indirectly suppressing fire occurrence. Over the past ca. 50 years, and more so after the demise of the social system in the 90's, pastoral activities have strongly decreased in several sectors of the Carpathians causing the re-expansion of *P. mugo* in the alpine treeline ecotone (Tsaryk et al., 2006; Nedelea and Comănescu, 2009; Solár and Janiga, 2013). The increasing biomass availability, together with the potential effect of more frequent heat waves in Central Europe in the coming decades (Schär et al., 2004), may thus lead to increased fire risk in the high elevation mountain environments of the Carpathians. However, how fire risk will develop in the mountain-pine thickets of the Carpathians will largely depend on the amplitude and nature of climate change, on the vegetation changes associated with the climate changes, and on land-use management.

5. Conclusions

This study provides the first long-term fire-episode reconstruction related to treeline variability in the Retezat Mountains and adds a valuable perspective on the impact of climate and land-use changes on high-altitude vegetation in European mountain regions. Results suggest that highest biomass burning occurred during the warmer and drier early Holocene,

when the treeline was rising towards its highest elevation. Fire frequency spatially reflected the different microclimates of the north and south slopes and the positions of the sites in relation to the treeline ecotone. Anthropogenic vegetation change increased during the past ca. 2000 years, especially on the south slope, and is related to a moderate biomass burning increase until ca. 1300 cal yr BP. Thereafter, more intensive land-use activities in the high-mountain areas led to the indirect suppression of local-fire occurrence due to the thinning and/or cutting of *P. mugo* thickets (fuel suppression) around the treeline. With the on-going land-abandonment in economically marginal areas, such as those at the treeline ecotone, the natural reforestation by *P. mugo* thickets may potentially lead to moderately higher fire occurrences.

Acknowledgements

Data of recent forest fires were provided by the European Forest Fire Information System e EFFIS (<http://effis.jrc.ec.europa.eu>) of the European Commission Joint Research Centre. This study was supported by the French ANR (OBRESOC project; ANR-09-CEP-004-01/OBRESOC), the Hungarian Scientific Research Fund (PROLONG project; OTKA NF101362), and by an STSM grant to IV by the EUCOST Action INTIMATE (ES0907). We thank the support of the Retezat National Park. We are also grateful for the constructive suggestions from three reviewers.

Figures and Tables

Fig. 1. Map of the location of the study area in the Carpathians (a) and the study area. Map from National Geographic's MapMaker Interactive

(<http://mapmaker.education.nationalgeographic.com/>).

Fig. 2. Fire-episode reconstruction for Lake Brazi (modified from Finsinger et al., 2014) and Lake Lia. Upper and lower panels: reconstructed fire-episode histories based on macroscopic-

charcoal accumulation rates by area (macro-CHAR_A) and by counts (macro-CHAR_C); middle panel: macroscopic charcoal concentrations (pieces cm⁻³). Grey lines in top and bottom panels: macro-CHAR residuals (macro-CHAR_i e macro-CHAR_{back}); red line: threshold; red crosses: significant charcoal peaks that survived the screening tests; grey dots: insignificant charcoal peaks. Pink vertical bands highlight the CHAR_A values that exceed the 99th percentile threshold within 900-year moving windows, i.e. potential CHAR_{peaks}. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Fig. 3. Comparison between change-point analysis based on charcoal-accumulation rates by counts (CHAR_C; top) and by area (CHAR_A; middle) and sample deposition times for Lake Brazí (left) and Lake Lia (right). Black lines in top and middle panels: CHAR records,

vertical blue lines: change points in the CHAR records, empty circles: change points in the randomly generated CHAR_{sedrate} records, grey shaded areas: periods of higher CHAR values. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

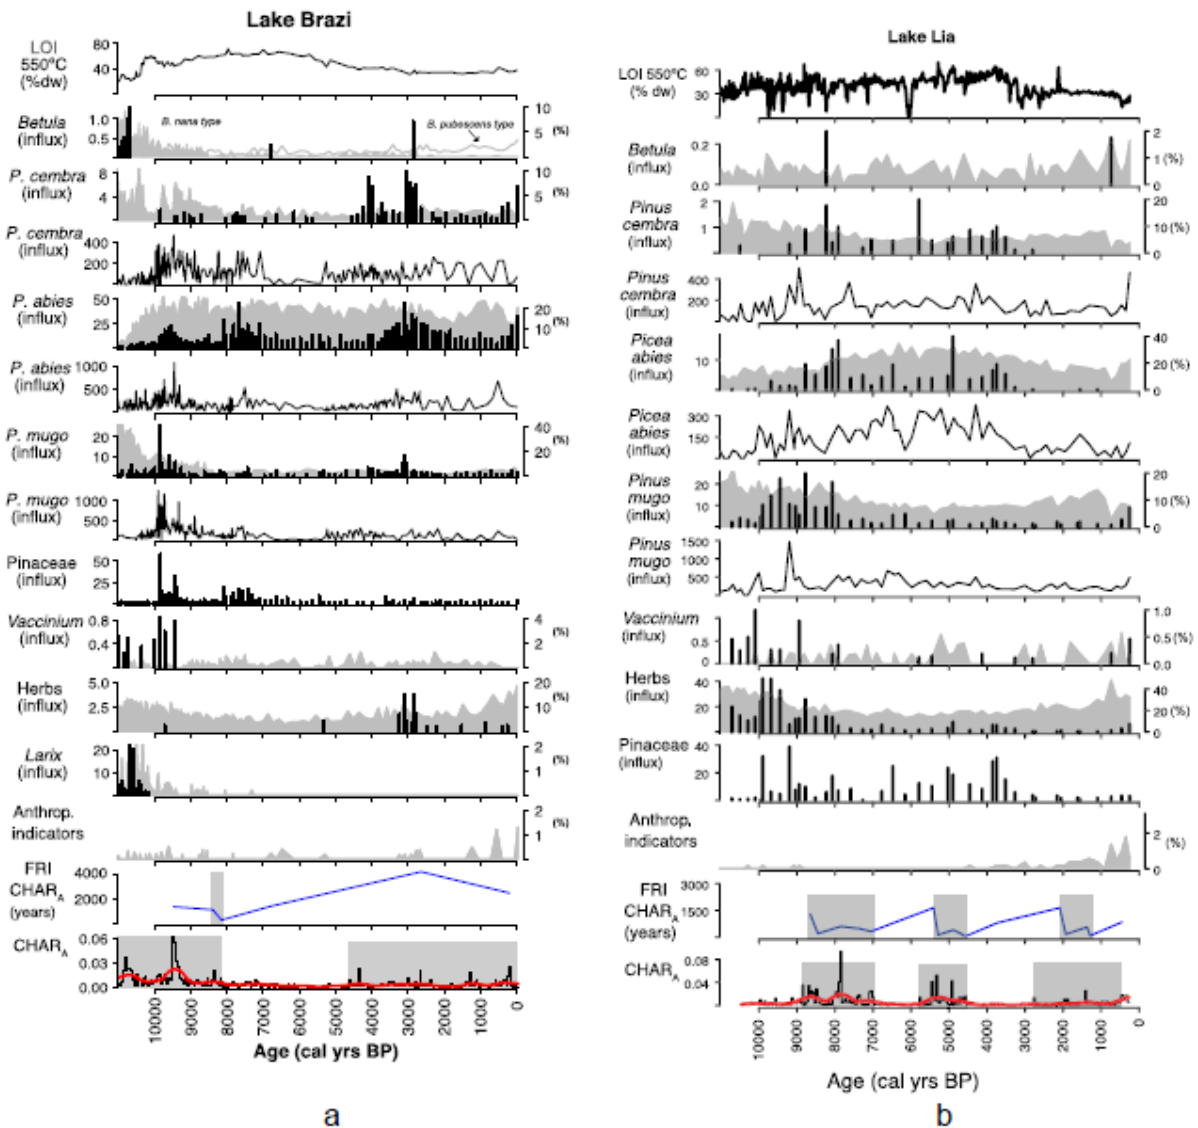

Fig. 4. Summary diagrams for Lake Brazí (a) and Lake Lia (b) with loss-on-ignition (LOI, % dry weight), the most relevant plant macrofossil taxa (black histograms; accumulation rates), pollen taxa (grey shaded curves; percentages), conifer stomata (black line; accumulation

rates), inferred fire-return intervals (FRI based on CHAR_A), and total CHAR_A . Grey shaded areas in the FRI and CHAR_A plots highlight periods of shorter FRIs and periods of higher biomass burning as inferred based on the change-point analyses (see Fig. 3). In Lake Brazí *Betula* pollen grains were identified as either *Betula nana* type (grey area) or *Betula pubescens* type (grey line).

Fig. 5. Comparison between chironomid-inferred July-air temperature from Lake Brazí (top) (Tóth et al., 2015) and fire histories inferred based on $\text{CHAR}_{\text{back}}$ and FRIs at Lake Brazí and Lake Lia. Grey shaded areas: periods of shorter FRIs at Lake Lia.
