ABSTRACT

2012 DR₃₀ is a recently discovered Solar System object on a unique orbit, with a high eccentricity of 0.9867, a perihelion distance of 14.54 AU and a semi-major axis of 1109 AU, in this respect outscoring the vast majority of trans-Neptunian objects. We performed Herschel/PACS and optical photometry to uncover the size and albedo of 2012 DR₃₀, together with its thermal and surface properties. The body is 185 km in diameter and has a relatively low V-band geometric albedo of ~8%. Although the colours of the object indicate that 2012 DR₃₀ is an *R1* taxonomy class TNO or Centaur, we detected an absorption feature in the Z-band that is uncommon among these bodies. A dynamical analysis of the target's orbit shows that 2012 DR₃₀ moves on a relatively unstable orbit and was most likely only recently placed on its current orbit from the most distant and still

highly unexplored regions of the Solar System. If categorised on dynamical grounds 2012 DR₃₀ is the largest Damocloid and/or high inclination Centaur observed so far.

Key words. Kuiper belt: general – individual (2012 DR 30)

1. Introduction

2012 DR₃₀ was discovered on February 26, 2012 (MPEC 2012-D67) as part of the Siding Spring Survey¹. Shortly after the discovery of 2012 DR₃₀, it was realised that the object was identical to the object 2009 FW₅₄. As a result of that identification, it has been possible for the object's orbit to be determined with relatively high precision, based on 142 observations made between February 2008 and April 2012. The orbit is rather peculiar with a semi-major axis of $a = 1109$ AU, eccentricity of $e = 0.9869$ and inclination of $i = 78^{\circ}00'$. The object is currently close to its perihelion, $q = 14.54$ AU on its ~ 37 thousand-year long orbit (see also the Minor Planet Center page of 2012 DR₃₀²).

Following Gladman et al. (2008), 2012 DR₃₀ would most likely be classified as a Scattered Disk Object. However, the Gladman et al. scheme was mainly focussed on understanding the behaviour of objects originating in the trans-Neptunian region, and so such a classification would naturally lead the reader to infer an origin for 2012 DR₃₀ in the trans-Neptunian population. On the other hand, Brasser et al. (2012) consider objects on orbits like that of 2012 DR₃₀ to be high inclination Centaurs, and, along with Emel'yanenko et al. (2005), have suggested that the origin for these objects could well be the inner Oort cloud, rather than the trans-Neptunian belt. Currently, only three objects are categorised as high inclination Centaurs: 2002 XU₉₃, 2008 KV₄₂ and 2010 WG₉ (Brasser et al., 2012).

Considering the high eccentricity and inclination of 2012 DR₃₀'s orbit, another way to categorise it might be to consider it a high-perihelion, long-period comet since it shares many characteristics with those objects (as its perihelion distance is ~ 15 AU, it is not classified as having cometary dynamics according to the Gladman et al. (2008) scheme that requires $T_J < 3.05$ and $q < 7.35$ AU). Many objects moving on typical Centaur orbits were classified as comets on the basis of cometary activity at discovery – this has not, to date, been observed in the case of 2012 DR₃₀.

Given the similarity of the orbit of 2012 DR₃₀ to those of the long period comets it is worth considering a different mechanisms proposed to emplace objects in such orbits. An object with an aphelion distance of ~ 1000 AU is typically considered to be too tightly bound to the Sun for its orbit to be significantly perturbed by the influence of the galactic tide or close encounters with passing stars (processes which are considered far more important at aphelion distances of $\sim 10,000$ AU, or greater). The orbital evolution of such objects is thought to currently be driven by chance encounters with the giant planets: cometary bodies moving on short-period orbits within the outer Solar System are regularly scattered to longer period orbits – or even entirely ejected from the Solar system (Horner et al., 2004b). Typically, however, objects on highly eccentric orbits (with aphelia at thousands, or tens of thousands of AU) are thought to have been be recently injected from the Oort cloud. The classical route through which such objects are emplaced to their current

* *Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

¹ <http://www.mso.anu.edu.au/rmn/index.htm>

² http://www.minorplanetcenter.net/db_search/show_object?object_id=2012+dr30

orbits involves their injection from the outer Oort cloud, where their orbits can be strongly modified by the influence of the galactic tide and the gravitational influence of passing stars (e.g. Wiegert & Tremaine, 1999; Dones et al., 2004; Rickman et al., 2008).

Whilst this mechanism is good at explaining the observed distribution of long-period comets with perihelion distances in the range 5–10 AU, it has great difficulties explaining the existence of the high-inclination Centaurs (as described by e.g. Brassier et al., 2012). These objects display high perihelion distances (e.g. 14.54 AU, in the case of 2012 DR₃₀), which would typically be considered as too distant for Jupiter and Saturn to easily decouple the object’s orbital evolution from the influence of passing stars and the galactic tide. The aphelion distance of these objects, however is significantly too small for them to have been injected to their current orbit by a passing star or by the galactic tide. For this reason, a number of authors have proposed that such objects are instead sampling the inner Oort cloud population (e.g. Emel’yanenko et al., 2005; Brassier et al., 2012).

Since 2012 DR₃₀ falls very close to the tenuous $q \approx 15$ AU boundary between those objects that could theoretically be decoupled from the outer Oort cloud by the influence of Jupiter and Saturn, and those objects that could not be captured in this way, it is clearly had to definitively argue for one particular origin over the other. In either case, however, it seems reasonable that it could well be a relatively recent entrant to the inner reaches of the Solar System.

On dynamical grounds 2012 DR₃₀ also shows similarities to the group of Damocloids which are thought to be inactive Halley-type or long-period comets. According to the definition given by Jewitt (2005) objects in this group have a Tisserand-parameter relative to Jupiter $T_J \leq 2$, and indeed, this parameter for 2012 DR₃₀ is $T_J = 0.198$. On the other hand, these objects have perihelion distances typically $q \leq 5$ AU and are small ($H_V > 10$) in most cases, unlike 2012 DR₃₀ ($H_V \approx 7$). Some of the few exceptions are the three high inclination Centaurs mentioned above which are also Damocloids according to their T_J -s. These objects should be relatively large ($H_V \approx 8^m0-9^m0$). A reliable size estimate is only available for 2002 XU₉₃, which has an effective diameter of 164 ± 9 km, based on thermal emission measurements with the Herschel Space Observatory (Santos-Sanz et al., 2012). The surfaces of the Damocloids are among the darkest ones known in the Solar System – the objects for which albedos are known so far all have $p_V \approx 0.04$ (see Jewitt, 2005; Santos-Sanz et al., 2012).

In the case of 2012 DR₃₀ it is clearly interesting to consider whether there might be any observational evidence that could support one possible origin over another, particularly if 2012 DR₃₀ could be recently placed to its current orbit from the inner Oort cloud. Apart from dynamical behaviour, evidence may also come e.g. from surface characteristics reflecting the different evolutionary paths this object might have taken. In this paper we investigate the basic physical properties of 2012 DR₃₀ with the help of thermal emission and optical follow-up photometry observations and try to relate these to the dynamics of the orbit of this peculiar object.

2. Observations and data reduction

2.1. *Herschel/PACS observations*

Thermal emission of 2012 DR₃₀ was observed with the PACS photometer camera (Poglitsch et al., 2010) of the Herschel Space Observatory (Pilbratt et al., 2010) using the time awarded in a DDT

Table 1. Summary of Herschel/PACS, WISE and MPG/ESO 2.2m observations. The columns of the table are: (1) Telescope and instrument; (2) Observation identifier; (3) Photometric band(s), identified with the nominal wavelength(s); (4) Start date and time of the observation (UTC); (5) Start time of the observation (Julian Date); (6) Heliocentric distance (AU); (7) Target distance (AU); (8) Phase angle (deg). The data of the last three columns were taken from NASA’s Horizons Database. Herschel observations lasted for 1414 s.

proposal exclusively for 2012 DR₃₀ (proposal ID: DDT_ckiss.2). The observations were performed in mini-scanmap mode, homogeneously covering a field of roughly 1’ in diameter (Fig. 1). This mode is suited for our needs and offers more sensitivity than other observation modes of the PACS photometer (Müller et al., 2010).

The reduction of raw data was performed in the Herschel Interactive Pipeline Environment (HIPE, Ott 2011) using an optimized version of the PACS bright point source pipeline script without the application of proper motion correction due to slow motion of the target relative to the telescope beam size during a single OBSID (<1’). We derived single epoch co-added images in each Herschel/PACS band, as well as differential and ’’double-differential’’ images combining the data of the two epochs in order to get rid of the confusion due to the sky background. Differential images are created by subtracting the co-added image of the second visit from that of the first visit image of the same band. This eliminates the background and leaves a positive and a negative beam of the target on the image. The ideal matching of the two image frames is obtained using a fluctuation minimalisation method. To create a double differential image, a copy of the differential image is folded and shifted in a way that the positive beams of the two visits are matched in position

Table 2. Summary table of the Herschel photometry results. Visit-1 and Visit-2 refers to the two epochs of observations (see Table 1). Visit-1 and Visit-2 differential fluxes are derived from the *differential*, background eliminated maps, performing photometry on the positive and negative beams of the target independently. The *double differential* fluxes are derived from the double differential maps performing photometry on the central, combined beam.

Band (μm)	Epoch	F_{coadd} (mJy)	F_{diff} (mJy)	F_{ddiff} (mJy)
70	Visit-1	92.83 \pm 1.45	91.80 \pm 0.88	88.56 \pm 0.62
70	Visit-2	89.41 \pm 1.25	87.18 \pm 0.88	
100	Visit-1	64.12 \pm 1.46	63.87 \pm 1.20	62.40 \pm 0.91
100	Visit-2	66.22 \pm 1.94	62.08 \pm 1.20	
160	Visit-1	37.83 \pm 2.38	32.82 \pm 1.34	34.48 \pm 1.13
160	Visit-2	40.37 \pm 2.66	36.52 \pm 1.34	

and then co-added, providing a positive beam with the average flux of the target, plus two negative beams on the sides with fluxes about half the central, positive beam (the photometry is performed on the central beam). The procedure to create these images, and also the photometry of the target was performed in the same way as it is described in detail in Pál et al. (2012); Vilenius et al. (2012); Santos-Sanz et al. (2012). The photometric fluxes we obtained are summarized in Table 2.

Fig. 1. False colour images of Herschel/PACS photometer with the nominal wavelengths of 70 (blue), 100 (green) and 160 μm (red). Left and middle panels represent the Visit-1 and Visit-2 images, respectively, in the corresponding bands, while the right column shows the differential image. 2012 DR₃₀ is in the centre of the Visit-1 and Visit-2 images, and is seen as a pair of bright/dark spots on the differential image.

2.2. MPG/ESO 2.2 m optical follow-up at La Silla

We performed photometric measurements of 2012 DR₃₀ in a service mode Max-Planck-Institut für Astronomie (MPIA) DDT observation at La Silla Observatory, Chile, using the MPG/ESO 2.2m telescope (PID 089.A–9031(A)).

Data were taken with the Wide Field Imager on June 6, 2012 and consist of images in filters B (BB#B/123_ESO878, 60s), V (BB#V/89_ESO843, 60s), R (BB#Rc/162_ESO844, 60s), I

(BB#I/203_ESO879, 60s) and Z (BB#Z+/61_ESO846, 280s). We used three individual exposures for the B, V, R and I filters each, while the Z had six exposures. The Cambridge Astronomical Survey Unit pipeline (Irwin & Lewis, 2001) was used to combine the bias frames and dome flat fields, obtained on the same night, into master bias and master flat frames which were then used for the bias subtraction and flat fielding. Preliminary source extraction and astrometry, crossmatched with the 2MASS point source catalogue (Skrutskie et al., 2006), were determined for all the reduced frames allowing the multiple observations per filter to be each stacked into a deeper image. The multiple I and Z frames were median combined to form fringe frames which were then used to defringe the individual I and Z frames before stacking. The source extraction and astrometry were then repeated and refined on the stacked frames with an accuracy of better than 0".2. The seeing was typically better than 1".3 during the observations.

BVRI standard stars were taken from SA 104 in the Landolt (1992) catalog to measure the photometric nature of the night. A field overlapping with SDSS was observed to provide a reference for the Z band. Z images were then transformed to SDSS *z* magnitudes following two methods: (i) synthetic *z* magnitudes calculated for field stars (Rodgers et al., 2006), and (ii) standard stars in the SDSS stripe #1540 (RA= 11:29:30 Dec= -07:00:02) in 15° vicinity of 2012 DR₃₀. The two methods gave consistent zeropoints within ± 0.02 mag. Atmospheric extinction coefficients were taken from ESO website for La Silla³.

2.3. WISE observations of 2012 DR₃₀

2012 DR₃₀ was not seen by the Wide-field Infrared Survey Explorer (WISE Wright et al., 2010) according to the MPC entries and the WISE search tools. It might be that 2012 DR₃₀ was not yet known at the time the Solar System search programmes were executed (see e.g. Mainzer et al., 2011) or that it simply was not recognised as moving target due to its slow apparent sky motion of only 1-5"/h. But based on the PACS measurements and flux extrapolations to the WISE W3 (11.56 μ m) and W4 (22.09 μ m) bands it became clear that WISE must have seen 2012 DR₃₀.

We found the source *J103104.77+005635.9* within 1" of the 2012 DR₃₀ path in the WISE all-sky source catalog⁴. The W3 and W4 magnitudes are 12.037 and 6.900, respectively. The WISE image catalog shows a sequence of several detections in W4, but the source is clearly moving and appears elongated. We therefore used the WISE all-sky single exposure (L1b) source table which includes several source detections along the apparent sky path of 2012 DR₃₀. The seven W3-detections (with S/N >2) and the nine W4-detections were taken in the period MJD 55341.85947 – 55342.58708 (mean: 55342.24166). The weighted mean W3-band magnitude was $10^m88 \pm 0^m22$ and the typical S/N was about 3, the weighted mean W4-band magnitude was $5^m95 \pm 0^m16$ and the typical S/N was about 10.

We converted the observed magnitudes via the Vega model spectrum into fluxes. Due to the red colour of 2012 DR₃₀ (compared to the blue calibration stars) there is an additional correction needed (see Wright et al., 2010) and the W3-flux has to be increased by 17% and the W4-flux has to be lowered by 9%. It is also necessary to apply a colour correction, which we calculated via a TPM prediction of the spectral energy distribution of 2012 DR₃₀ (corresponding roughly to a black

Table 3. Summary on the calculation of input fluxes and flux uncertainties. The columns are: (1) Instrument; (2) Band and/or reference wavelength; (3) Colour correction factor; (4) flux correction; (5) absolute calibration uncertainty; (6) measured flux; (7) monochromatic flux used in the thermal models (see also Sect. B. Note that in the case of the Herschel/PACS the uncertainties of the input fluxes are dominated by the absolute calibration uncertainties.

Instrument	Band/Wavelength (μm)	C_λ	r_{corr}	r_{cal}	F_{meas} (mJy)	F_{inp} (mJy)
WISE (W3)	11.6 μm	2.35 \pm 0.24	1.17	0.10	1.29 \pm 0.26	0.64 \pm 0.16
WISE (W4)	22.1 μm	1.00 \pm 0.01	0.91	0.10	34.50 \pm 5.10	31.4 \pm 5.6
Herschel/PACS	70 μm	0.99 \pm 0.02	1.00	0.05	88.56 \pm 0.62	89.45 \pm 3.29
Herschel/PACS	100 μm	1.01 \pm 0.02	1.00	0.05	62.40 \pm 0.91	61.78 \pm 2.39
Herschel/PACS	160 μm	1.045 \pm 0.020	1.00	0.05	34.48 \pm 1.13	33.00 \pm 2.07

body temperature of slightly above 100 K). The colour correction factors are 2.35 (\pm 10%) in W3 and 1.00 (\pm 1%) in W4. The large error for the W3 colour correction is due to the uncertain shape of the SED at these short wavelengths. We also added a 10% error for the absolute flux calibration in W3 and W4 which was estimated from the discrepancy between red and blue calibrators (Wright et al., 2010) and we combined all errors quadratically. The final mono-chromatic flux densities at the WISE reference wavelengths are listed in Table 3.

2.4. Light curve observations

We obtained visible-light imagery of 2012 DR₃₀ with queue observations on the 2 m Faulkes South telescope at Siding Spring Observatory, NSW. The Spectral camera of Faulkes South that we used has a plate scale of 0.304 arcsec/pixel, with a 4k \times 4k CCD array, giving a field of view of 10.5 arcmin.

We observed 2012 DR₃₀ through the Sloan Digital Sky Survey r' filter on four nights, as detailed in Table A.1. On each night, consecutive 300 s exposures were obtained with 2012 DR₃₀ centred on the array; the 2 \times 2 binning set a readout time between exposures of 22 s. The rate of motion of 2012 DR₃₀ across the sky was 0.9''/hr (a quarter-pixel, 75 milliarcsec, in 5 minutes), which kept it well within the seeing disk of \sim 2'' over each integration. Due to the low altitude of 2012 DR₃₀, the longest continuous set of observations were made over less than two hours. 34 integrations were made in total, excluding nine images where the seeing deteriorated below where 2012 DR₃₀ could be detected.

Bias subtraction, flatfielding and astrometry were provided by the standard Faulkes queue pipeline. The flatfielding varied in quality due to proximity to the Moon on some of the nights, creating a pocked "golf course" effect in places, but 2012 DR₃₀ did not fall on any problematic locations in these observations. We then used SExtractor (Bertin & Arnouts, 1996) to obtain the flux of 2012 DR₃₀ from the reduced images.

The 10 arcmin field of view provided ample suitably bright field stars, from which we selected eleven to act as comparison stars and cancel the effects of atmospheric variability (Table A.2). The selection was based on their photometric stability, lack of saturation, no blends or other close stars, and their spatial distribution on the field; the mutual relative photometry of these eleven

Fig. 2. Comparative photometry of 2012 DR₃₀ over four nights. The error bars are given relative to the internally consistent photometry (left ordinate), and is dominated by the photon noise, found via SExtractor’s FLUXERR_APER (RMS error vector for aperture flux) values. The absolute magnitude (right ordinate) is tied to the APASS catalogue, which had up to an $0.2 m_r$ variation in the shift required for the standard stars, so it is provided for guidance rather than high precision.

stars varied by less than 0.01 mag across all the observations. We then measured the differential brightness variation of 2012 DR₃₀ against these stars.

The field on which 2012 DR₃₀ fell during our observations (R.A. = $10^h 16^m$, decl. = $-17^\circ 05'$) was too far south to be within the SDSS photometric catalog. We instead used the AAVSO Photometric All-Sky Survey (APASS) Data Release 6 survey catalog for absolute calibration of the magnitudes of the comparison stars. Four had matches within $2.2''$ - $0.5''$ in the catalogue (Table A.2); these matches were confirmed by visual inspection of the images. The known catalogue magnitudes allowed us to tie the zeropoint of the differential variation of 2012 DR₃₀ to an absolute magnitude. The scatter in the shift between the observed stellar magnitude and the catalogue value for the four comparison stars was 0.2 magnitudes; we therefore note that the internal precision in the relative photometry is much greater and provides a better measure of the variability of 2012 DR₃₀.

We used these comparative photometric measurements of 2012 DR₃₀ to construct a light curve (Fig. 2). This showed very little variation and indicated an upper limit of $0^m 004$ 1-sigma variability when only the standard deviation of the target’s r band brightness values are considered. Note that the uncertainty of the individual measurements are dominated by the error of absolute calibration with a typical value $0^m 05$ (see also Fig. 2). We tried to fit a rotation period but the periodogram showed aliases only at one- and half-day periods, which would be spurious effects from the cadence of the observations. As a summary of these observations we can conclude that we have not been able to detect the light curve of 2012 DR₃₀ at the $0^m 05$ level in the r band. It would be useful in the future to obtain a further light curve in multiple colours (g and r) to confirm if there is any more subtle colour-dependent variability, which could indicate either surface composition or topographic variation.

Table 4. Absolute magnitudes and colours derived for 2012 DR₃₀ from the MPG/ESO 2.2 m observations.

3. Characteristics derived from visual range and infrared measurements

3.1. Absolute brightness, colours and phase correction

We used the MPG/ESO 2.2m to calculate H_V of 2012 DR₃₀ as well as 66 points of V-band data in the Minor Planet Center database as auxiliary data to calculate the absolute brightness of 2012 DR₃₀. As these data points cover the phase angle range of $1^\circ 0 < \alpha < 3^\circ 7$, we were able to fit the slope parameter with a straight line and we obtained $\beta = 0.137 \pm 0.089$. We assigned a general error bar of $0^m 3$ to the MPC V-band data points, the median difference reported between MPC and well-calibrated photometry (Romanishin & Tegler, 2005; Benecchi et al., 2011).

The MPG/ESO 2.2 m telescope observations provided absolute magnitudes and colours, as listed in Table 4. Using the V-band brightness, the geometry information at the observation epoch and the β value we obtained from MPC data we calculated the V-band absolute brightness of 2012 DR₃₀. The heliocentric and observer-to-target distances and the phase angle of the observation were $r = 14.678$ AU, $\Delta = 14.70$ AU and $\alpha = 3^\circ 952$, respectively. Based on the observed brightness of $V = 19^m 254 \pm 0.023$ we obtained $H_V = 7^m 04 \pm 0^m 35$.

3.2. NEATM models of the thermal emission

We used the Near-Earth Asteroid Thermal Model (NEATM, Harris 1998) to estimate the main characteristics of the target combining the fluxes of its reflected light and thermal infrared emission. The input fluxes used for the NEATM model (as well as for the thermophysical model discussed in the next subsection), are calculated from the observed fluxes in the way described in Sect. B.

In our NEATM modelling the beaming parameter η , in addition to the effective diameter and geometric albedo, was treated as a free parameter and therefore fitted to our data points. The quality of the fit is characterised by the reduced χ^2 values (described e.g. in Vilenius et al., 2012).

We considered two sets of data points. In the first one we used the combined, "double differential" Herschel/PACS fluxes in the 70, 100 and 160 μm bands (three data points, see Table 3), while in a second set we used the 11 and 22 μm WISE fluxes as well (altogether five data points). The "best-fit" result is presented in Fig. 3. The "PACS only" fit provides the best-fit parameters of $D_{\text{eff}} = 173 \pm 17$ km, $p_V = 9.1^{+4.4}_{-2.7}\%$ and $\eta = 0.57^{+0.28}_{-0.21}$. Using the five "PACS+WISE" data points the best-fit quantities are $D_{\text{eff}} = 188.0 \pm 9.4$ km, $p_V = 7.6^{+3.1}_{-2.5}\%$ and $\eta = 0.813^{+0.074}_{-0.062}$.

The low value of the η parameter (~ 0.8) is very close to the canonical value 0.756 used for main belt asteroids and is different from the mean value of $\eta = 1.20 \pm 0.35$ in the trans-Neptunian population (Stansberry et al., 2008; Lellouch et al., 2012). Trans-Neptunian objects, however, show a rather wide range of beaming parameters. Recent results indicate an average value of $\eta = 1.11 \pm 0.15$ for Plutinos (Mommert et al., 2012), $\eta = 1.14 \pm 0.15$ for Scattered Disk Objects (Santos-Sanz et al., 2012) and $\eta = 1.47 \pm 0.43$ for Classical (Vilenius et al., 2012). Although the beaming parameters derived for Centaurs are rather similar to those of other trans-Neptunian object classes (with a median value of $\eta = 1.12 \pm 0.38$ Lellouch et al., 2012), there are a few Centaurs with η values close to or below that of 2012 DR₃₀, down to $\eta \approx 0.4$.

Fig. 3. Best-fit NEATM model considering the Herschel/PACS and WISE 11 μm and 22 μm input fluxes. The WISE fluxes were transformed to the PACS observations geometry.

3.3. Thermophysical modeling of the infrared emission

We also used a thermophysical model (TPM) approach (Müller & Lagerros, 1998, 2002, and references therein) to obtain the main surface characteristics of our target (size, albedo, thermal inertia, surface roughness), based on the Herschel/PACS and WISE data (for details of the present model see Müller et al., 2010). As the object was bright, and photometry could be performed with a relatively high signal-to-noise ratio, we used the thermal fluxes of the two epochs independently (the differences in the fluxes at the two epochs might reflect rotational variations). Unfortunately the rotation period could not be inferred from the light curve observations (see Sect. 2.4). The results we obtained show that the object has a low thermal inertia below $4 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$ (assuming $P_{\text{sid}} = 6 \text{ h}$) or below $9 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$ ($P_{\text{sid}} = 24 \text{ h}$), except if we have seen it pole-on (in this latter case our model is not able to provide any constraints on the object's thermal inertia). These two rotation periods encompass the majority of the known TNO/Centaur rotation periods. We note from this that the influence of the rotation period on the derived results for 2012 DR₃₀ is very minor. A low surface roughness (very smooth surface) is not compatible with the observed fluxes, independent of spin-vector orientation, rotation period or thermal inertia. The possible size range is 183 - 198 km, using the requirement that reduced χ^2 -values can be allowed up to $\chi_r^2 = 1.38$ in the case of five independent measurement points. The possible albedo range is 0.060 - 0.085, allowing

the same χ_r^2 range and also including a $\pm 0^m 1$ error for the H-magnitude. Allowing for the full ± 0.35 mag error for H_V (see Section 3.1) would lead to a possible albedo range of 0.055 – 0.111 in our TPM analysis. The best fit TPM solution for equator-on geometry provides $\Gamma = 0.4 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$, high roughness, $D = 184.1 \text{ km}$ and $p_V = 0.078$, with a corresponding χ_r^2 -value of 0.58. The pole-on situation produces an even better fit with a χ_r^2 -value of 0.51, and with the corresponding size and albedo ranges of $D = 183 - 186 \text{ km}$ and $p_V = 0.070 - 0.085$ while in this case the thermal inertia is not constrained.

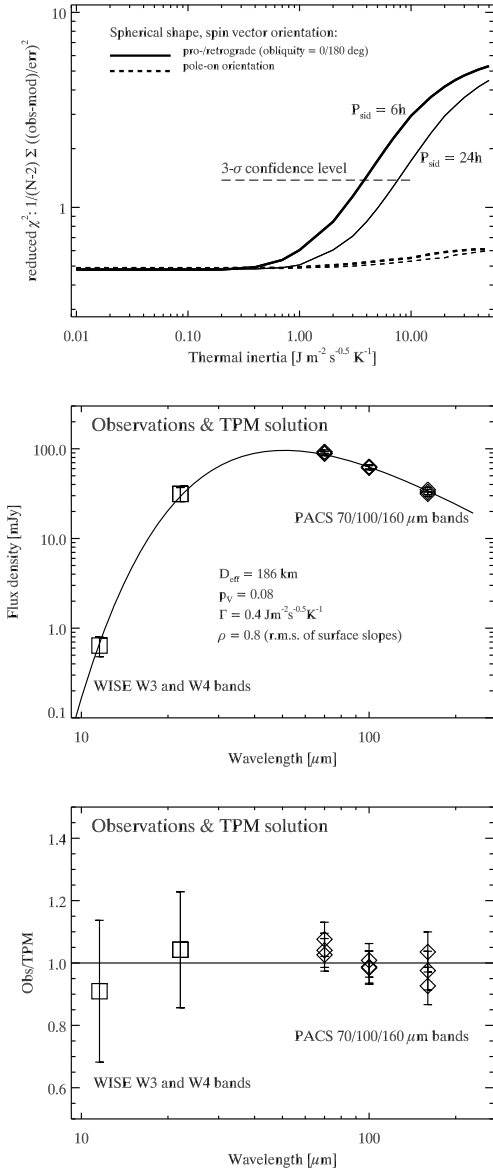

Fig. 4. (a) TPM analysis of all available thermal measurements. The reduced χ^2 -values are shown for two different spin vector orientations: equator-on (solid lines) and pole-on (dashed lines), each time for two different values for the rotation period. The 3- σ confidence level for the TPM fit to the observations is also shown. (b) the best TPM solution is shown together with the observed fluxes (c) the same model, but now shown in the observation/TPM picture.

Fig. 5. *Upper panel:* B-V versus V-R colours of 2012 DR₃₀ and those of the objects in the “MBOSS2” database (Hainaut et al., 2012). The symbols correspond to various dynamical classes of the trans-Neptunian object population and of comets, as follows: (1) red filled triangle: plutons; (2) open red triangle: other resonant objects; (3) filled red circle: cold Classicals; (4) filled orange square: hot Classicals; (5) filled yellow square: other Classicals; (6) filled dark blue circle: Scattered disk objects; (7) filled light blue circle: Detached objects; (8) open light blue triangle: Jupiter Trojans; (9) filled green circle: Centaurs; (10) filled black square: short period comets; (11) open black square: long peroid comets. The big black open circle represents the solar colours (Ramírez et al., 2012). *Lower panel:* The same as the upper panel, but now presenting the B-V versus R-I colours of 2012 DR₃₀ and the objects in the “MBOSS2” database.

3.4. Colours and visual reflectance

We plotted the B-V vs. V-R and B-V vs. R-I colours of 2012 DR₃₀ along with those of other outer Solar System objects using the MBOSS-2 database (see fig.5 in Hainaut et al., 2012). Compared to the colours of other bodies, 2012 DR₃₀ is certainly “blue” when its B-V colour is considered (close to the solar value), while it shows colours closer to the population average in R-I, and especially in V-R.

When comparing our observations of 2012 DR₃₀ to the observed colours of the Centaurs alone (the green filled circles in Fig. 5), we find that 2012 DR₃₀ has a noticeably lower B-V colour than any of the Centaurs in the MBOSS sample. In the other colours (V-R and R-I) its colours are not vastly different to those of the Centaurs, but are close to the “blue” side of the distributions. We note that the colours of 2012 DR₃₀ are in general very close to those of 2002 DH₅.

As dynamically 2012 DR₃₀ would also fit into the group of Damocloids (black symbols in Fig. 6) we also compared the colours of these objects with those of 2012 DR₃₀. While Damocloids seem to follow the main colour trend (blue dashed line) of the TNO taxonomy classes, the colours of 2012 DR₃₀ are rather different from those of the other group members. In addition we also plotted the average colours of S- and V-type asteroids. The colours of 2012 DR₃₀ are definitely different from the S-type colours, but are close to the colours of V-type asteroids (green and orange symbols in Fig. 6, respectively).

Fig. 6. (B-I) versus (V-R) colours of 2012 DR₃₀ (red filled circle with error bars) and some representative object types. Black data points represent the colours of some Damocloids by Jewitt (2005); blue triangles with errors bars correspond to the mean values of the BB, BR, RI and RR taxonomy classes of TNOs and Centaurs (Perna et al., 2010), from bottom-left to top-right, respectively; the green and orange points show the median colours of the olivine bearing S-type and V-type asteroids, respectively (Chapman et al., 1993). The big black open circle marks the solar colours (Ramírez et al., 2012). The errors bars of the individual Damocloid points correspond to the errors of the colour determination (Jewitt, 2005) while in the case of the taxonomy class median values they represent the standard deviation of the distribution.

Using the absolute brightness values derived from the MPG/ESO 2.2 m measurements we calculated normalized reflectance using the solar colours of the SDSS magnitude transformation page⁵. 2012 DR₃₀ is represented by the red curve in Fig. 7. The most obvious feature one can identify is the presence of a strong Z-band absorption feature which is not seen in any of the main TNO taxonomy classes. Some objects with methane on their surfaces show absorption in the Z-band due to the 890 nm CH₄ line. However, these are large and very high albedo objects, like Eris and Makemake (Alvarez-Candal et al., 2011; Brown et al., 2007, respectively). The normalized reflectivity curves of these objects are plotted in Fig. 7 as well. As 2012 DR₃₀-s geometric albedo is ~8 per cent only, it would be very challenging to construct a surface composition which can reproduce the observed reflectivity, since even a smaller amount of methane could increase the albedo considerably and this is incompatible with the present albedo of the object.

Z-band absorption, however, can be relatively easily reproduced if it is due to the presence of olivine or pyroxene (with the strongest absorbance at $\sim 1 \mu\text{m}$), as it is the case in S- and V-type asteroids. Concerning just the depth of the Z-band absorption, the reflectance of V-type asteroids resembles the most to that of 2012 DR₃₀, however, with a notably different spectral slope at the shorter wavelengths. On the other hand, reflectivities of V-type asteroids may be modified by space weathering effects (Hiroi & Sasaki, 2012; Binzel et al., 2004), resulting in a reflectance more sim-

⁵ <http://www.sdss.org/dr5/algorithms/sdssUBVRITransform.html>

Fig. 7. Normalized spectral reflectivity of 2012 DR₃₀ in the optical (red curve), in comparison with the main TNO taxonomy classes BB, BR, RI, and RR (dashed-dotted lines from bottom to top, Perna et al., 2010), and the TNOs Eris (purple curve Alvarez-Candal et al., 2011) and Makemake (dark blue curve Brown et al., 2007). In addition, the average reflectivities of the S- and V-type asteroids are also shown (green and orange curves, respectively, Chapman et al., 1993; Gaffey et al., 1993). Note the Z-band feature of 2012 DR₃₀ is unseen in the usual TNO taxonomy classes and could most readily be attributed to the presence of a reddened olivine-bearing surface (see the text for details).

ilar to that of 2012 DR₃₀. A-type asteroids have similar reflectance spectra due to olivine (DeMeo et al., 2009).

4. The dynamics of 2012 DR₃₀

In order to examine the dynamical behaviour of 2012 DR₃₀, we used the Hybrid integrator within the n-body dynamics package MERCURY (Chambers, 1999) to follow the evolution of the orbit under the gravitational influence of Jupiter, Saturn, Uranus and Neptune for a period of 4 Gyr into the future. Following a procedure established in earlier works (Horner et al., 2004a; Horner & Lykawka, 2010; Horner et al., 2012a,b) we created a suite of test particles distributed in even sized steps across the 3-sigma error ellipses of the objects best-fit orbit in perihelion distance, q , eccentricity, e , and inclination, i . In this way, we created a grid of $45 \times 45 \times 45 = 91,125$ test particles in q - e - i space, centred on the nominal best-fit orbit for 2012 DR₃₀. Each of these test particles was then followed in our integrations until it was removed from the system, either by colliding with one of the massive bodies (i.e. the Sun or one of the giant planets) or being ejected to a heliocentric distance of 10,000 AU.

It is immediately apparent (see Fig. 8) that 2012 DR₃₀ is moving on a relatively dynamically unstable orbit, and that the number of clones that survive, as a function of time, decays exponentially. Half of the test particles are removed from the Solar System within just 75.5 Myr. Only 16 of the test particles survived for the full 4 Gyr of our integrations - just 0.0176 per cent of the total! The exhibited instability is independent of the initial perihelion distance, eccentricity, and inclination tested (see Fig. 9), although this is not hugely surprising, given the remarkably small uncertainties in the orbit of the object. Nevertheless, this result is reassuring, in that it tells us that

Fig. 8. The decay of our population of 91,125 clones of 2012 DR₃₀ as a function of time. The left-hand panels show the decay of the number of surviving clones as a function of time, whilst those to the right show the same data as log-log plots. The upper panels show the decay across the full 4 Gyr of our integrations, while the lower plots show just the first 200 Myr of the evolution of our test particles. It is immediately apparent that 2012 DR₃₀ is moving on a dynamically highly unstable orbit, with fully half the test particles being ejected from the Solar System within the first 75.5 Myr of the integrations. Such instability is not unexpected, given that 2012 DR₃₀s orbit crosses those of Uranus and Neptune.

Fig. 9. *Upper panel:* The mean lifetime of clones of 2012 DR₃₀, as a function of their initial perihelion distance and eccentricity. Each square of this plot shows the Log₁₀ of the mean lifetime of all 45 test particles that began the simulations at that particular a–e coordinate. The hollow box shows the location of the nominal best-fit orbit for 2012 DR₃₀, while the black lines that extend from that box show the 1-sigma errors in a and e for that best fit orbit.

Lower panel: The same as the upper panel but for inclination instead of eccentricity. We note that the stability of 2012 DR₃₀ does not vary significantly as a function of the initial eccentricity or inclination and perihelion distance used, a reflection of the relatively high precision with which the objects orbit is known.

Fig. 10. The total number of clones (Y) that spent at least X years closer to the Sun than 100 AU. The left plots show the data on a linear scale, while those to the right show it as log-log plots.

the dynamical behaviour we observe for the object is truly representative, in contrast to previous studies of Solar System objects such as the Neptun trojan 2008 LC₁₈, whose long-term behaviour was strongly dependent on the initial conditions considered (Horner et al., 2012a).

With our large dynamical dataset on the evolution of 2012 DR₃₀, it is possible to work out the frequency with which clones of that object become Earth-crossing objects, or how much time they spend approaching the Sun to within a given distance. Since dynamical evolution under the influence of gravity alone is a time-reversible process, this can then give us some indication of the likelihood that 2012 DR₃₀ has, in the past, occupied such orbits, as well as enabling us to estimate how long it has already spent within a given heliocentric distance.

Taken over all the clones in our runs, the mean clone lifetime was 124.26 Myr. As the clones of 2012 DR₃₀ evolved, they diffused in orbital element space such that 10808 became Earth-crossing objects at some point in their evolution, albeit typically only for very short periods of time. Just over a third of the test particles evolved onto orbits with perihelia under the control of Jupiter (i.e. within a heliocentric distance of ~ 6 AU), a result entirely in keeping with previous studies of the Centaurs (Horner et al., 2004a).

Given that 2012 DR₃₀ currently spends the great majority of its time at vast heliocentric distances, it is interesting to ask what fraction of its life it has likely spent closer to the Sun than a given heliocentric distance. Over the entirety of our runs (91,125 test particles with a mean lifetime of 124.26 Myr), we find that the mean amount of time clones spent at heliocentric distances of less than 1 AU was just ~ 1.5 years ($\sim 1.2 \times 10^{-6}$ % of their lifetime). The mean time spent within 10 AU of the Sun was $\sim 4,400$ years ($\sim 3.6 \times 10^{-3}$ % of their lives), while the mean time spent within 100 AU was ~ 3.3 Myr (~ 2.7 % of their lifetime).

In terms of the time spent at less than 100 AU, our simulations reveal a wide spread of outcomes - from those objects that spend just a few hundred years within 100 AU before being ejected from the Solar System to those few that spend well over a billion years in that region. In Fig. 10, we plot

the number of clones that spend at least a certain amount of time within 100 AU of the Sun, as a function of the total time elapsed within that heliocentric distance.

We note that, although the mean amount of time spent within 100 AU is ~ 3.3 Myr, this mean is heavily biased by a relatively small population of objects that are trapped onto relatively long lived orbits within 100 AU, which contribute vastly to the total time spent within that distance. Indeed, the *median* amount of time that clones spent within 100 AU of the Sun was just 18.8 kyr, with 975 of them spending under a thousand years within that distance, and almost 21,000 of the test particles spending under five thousand years within 100 AU.

5. Discussion

As 2012 DR₃₀ spent a relatively short time at small heliocentric distances (< 100 AU) it is interesting to consider whether the surface could have some memories of the long years spent at the far-out reaches of the Solar System. Volatiles kept on the surface might be one possibility.

As we mentioned it in Sect. 3.4, the 890 nm methane absorption band is at the right position to explain the strong Z-band absorption of 2012 DR₃₀. However, this possibility is ruled out by the relatively low albedo of the object. In addition to this, for an object with the size of 2012 DR₃₀ the methane volatility limit is at a ~ 100 AU distance from the Sun (Brown, 2011). Although 2012 DR₃₀ spends the vast majority of its lifetime beyond this heliocentric distance, in those short periods when it is close to its perihelion (closer than ~ 100 AU) the volatile escape rate of methane is so large that 2012 DR₃₀ certainly cannot retain this molecule on the surface even for a few thousand years, considering either Jeans or hydrodynamic escape rates (Schaller & Brown, 2007; Levi & Podolak, 2011). Replenishment of methane from subsurface resources is indeed a possibility, however, no cometary activity has been observed so far which otherwise would support this scenario. When mixed with or diluted in other ices (e.g. H₂O), the escape rate of methane could be significantly different. But even the clathrate hydrate of methane has a stability limit of 53 K at $p \approx 1$ nbar, and hence it cannot survive at the current distance of 2012 DR₃₀, about 15 AU (Gautier & Hersant, 2005). In addition, dilution of methane in other ices would decrease the depth of the absorption features.

Another reason to rule out methane on the surface could be that if 2012 DR₃₀ was originated from the Oort cloud and not from the trans-Neptunian region, then cosmic ray impacts on the surfaces so far away from the solar magnetosphere protection would be destructive for CH bonds and hence methane could not survive.

The very likely lack of methane on the surface favors a scenario in which the Z-band absorption is due to e.g. olivine or pyroxene, like in V-type asteroids – if the object were really V-type, this would certainly suggest a main belt origin. V-type asteroids are usually believed to be originated as impact ejecta from Vesta itself (Binzel & Xu, 1993), but due to its large size, it is very unlikely that 2012 DR₃₀ could be one of them (as indicated by its size, 2012 DR₃₀ might be a differentiated object itself). Probably the same is true for the relation of 2012 DR₃₀ to the very rare A-type asteroids that show similar reflectance spectra with strong olivine absorption, and are supposed to come from a completely differentiated mantle of an asteroid (DeMeo et al., 2009). Note that space weathering may also be an important factor in shaping the observable spectra and colours of these bodies (Lucas et al., 2012).

6. Conclusions

In this paper we determined the basic physical parameters (size, albedo) of 2012 DR₃₀, determined its visible colours and also discussed the dynamics of its orbit.

Considering dynamical evolution, it seems highly unlikely that 2012 DR₃₀ originated within the main belt. The most likely origins are either within the inner Oort cloud (as suggested for the high-inclination Centaurs by e.g. Emel'yanenko et al., 2005 and Brassier et al., 2012) or the outer Oort cloud (following the classical cometary capture route put forth by e.g. Wiegert & Tremaine, 1999). Despite the fact that it is highly unlikely, a main belt origin seems to explain more readily our observations that indicate a space-weathered V-type asteroidal surface, as discussed in the previous section. However, it is a question whether such a surface could be the result of a long time exposure of Galactic cosmic rays in the inner Oort cloud, beyond the protection of the heliosphere. A reflectance spectrum of 2012 DR₃₀ would be highly desirable to confirm and better characterise the Z-band absorption feature and likely rule out some of these possibilities.

Both the "PACS+WISE" NEATM and the thermophysical model results indicated a size of ~185 km and a V-band geometric albedo of 8 per cent for 2012 DR₃₀. With these characteristics, 2012 DR₃₀ is definitely the largest and highest albedo Damocloid or high inclination Centaur ever observed; and it is the fifth largest even among the Centaurs, just after 2002 GZ₃₂, Chariklo, Chiron and Bienor (Lellouch et al., 2012). This size and albedo is rather incompatible with the "extinct Halley-type comet" picture which is often used to explain the properties of Damocloids. The mere existence of 2012 DR₃₀ indicates that objects on Damocloid orbits may be of mixed origin and may not just be the once active nuclei of cometary bodies.

Appendix A: Astrometry and photometry data of the visual range measurements

Appendix B: Input fluxes for thermal modelling

We calculate the colour corrected flux from the measured flux using the C_λ colour correction factors and the $r_{corr,\lambda}$ flux correction factors. The colour correction factors of the Herschel data are calculated using the actual spectral energy distribution of the target according to Müller et al. (2011), while in the case of WISE data the correction factors are taken from Cutri et al. (2012). Then the corrected flux is:

$$F_{\lambda,cc} = r_{corr,\lambda} \cdot F_\lambda \cdot C_\lambda^{-1} \quad (\text{B.1})$$

and the uncertainty of the corrected flux is:

$$\frac{\delta F_{\lambda,cc}}{F_{\lambda,cc}} = \sqrt{\left(\frac{\delta F_\lambda}{F_\lambda}\right)^2 + \left(\frac{\delta C_\lambda}{C_\lambda}\right)^2} \quad (\text{B.2})$$

where δC_λ is the uncertainty of the colour correction factor. The final "input flux", used for the modeling of the thermal emission is the colour corrected flux, $F_{\lambda,i} = F_{\lambda,cc}$. However, the uncertainties of the absolute calibration have to be considered in the final "input" uncertainties:

$$\delta F_{\lambda,i} = \sqrt{\delta F_{\lambda,cc}^2 + (F_{\lambda,cc} \cdot r_{cal,\lambda})^2} \quad (\text{B.3})$$

where $r_{cal,\lambda}$ is the calibration uncertainty factor that is given as a certain fraction of the measured point source flux for all bands of the WISE and Herschel/PACS instruments. The actual values of all the factors mentioned above are summarized in Table 3, also listing the final input fluxes used the thermal emission modeling.
