

## Blood Gases and Blood pH in Spastic Bronchitis of Infants

By

F. VARGA and ZSUZSANNA HUTÁS

Department of Paediatrics, University Medical School, Pécs

(Received April 18, 1966)

This study had the purpose to observe changes in the blood gases, in the value of blood pH and in the acid-base equilibrium of infants caused by spastic bronchitis and by oxygen therapy.

It is fairly difficult to distinguish between the different grave diseases of the lower respiratory tract of infants, e.g. between bronchiolitis and bronchopneumonia. This applies also to spastic bronchitis, an infectious disease frequently accompanied by grave dyspnoea [2].

Although infantile bronchitis may be of various aetiology, its clinical manifestations are fairly uniform: the cough is insignificant or absent; inspiratory and expiratory dyspnoea is usually serious but responds readily to treatment with spasmolytic drugs and cortisone. The course of the disease and the prompt therapeutic result offer good clues for *a-posteriori* diagnosis. Table I shows the principal clinical symptoms encountered in the material of this study.

### MATERIAL AND METHOD

The material consisted of 15 babies aged from 1 to 16 months. Serial numbers

refer to the same patients in all Tables. The highest rectal temperature was 38.6°C, but only three infants had fever exceeding 38°C. Respiration rate was between 40 and 80/min., mean, 56. The average pulse rate amounted to 145/min. All the patients presented both expiratory and inspiratory serious dyspnoea. All but four were cyanotic. The sensorium was confused in the gravest cases, while the others displayed symptoms of grave hypoxia such as restlessness and alarm. (Restlessness is considered a more reliable sign of hypoxia than cyanosis [5]). Six patients had unilateral, and two bilateral, maxillary sinusitis; puncture yielded copious purulent discharge in all these cases. X-ray revealed deeply situated diaphragms, and rich perihilar markings in otherwise clear lung fields. In addition, moderate atelectasis was found in the lower lung fields of four patients. Auscultation yielded poor findings; apart from prolonged expiration, moderate bubbling rales were heard in some cases. Treatment with cortisone and antibiotics usually relieved the dyspnoea in 24 hrs, and ensured full recovery in five to six days. There was one exception: a baby of 7 weeks who had been moribund at admission died two days later. (Table 1.)

Oxygen was administered by means of a glass funnel placed above the face of the babies so as to allow the taking of blood samples from the temporal arteries. The percentage composition of the oxygen was, therefore, variable. Blood was usually drawn at admission (i.e. prior to treat-

ment) and then in the fifth minute of O<sub>2</sub> administration. O<sub>2</sub> tension, arterial pH and the other parameters were determined by means of Astrup's apparatus [1], while SCHOLANDER's micromethod [6] was used for the volumetric determination of blood gases. CO<sub>2</sub> tension was computed by NUN's interpolation technique with the SIGGAARD-ANDERSEN nomogram (3,8).

## RESULTS

Values for blood gases, blood pH and other parameters found before treatment are assembled in Table II.

(i) Oxygen tension (pO<sub>2</sub>) was decreased in all patients, and even conspicuously low in certain cases.

O<sub>2</sub> saturation of the arterial blood was correspondingly low in most cases. O<sub>2</sub> saturation below 70 per cent is known to cause grave hypoxia and is frequently fatal in adults. Mean arterial O<sub>2</sub> saturation was 66 per cent in the present material; despite the hypoxia there was but a single fatal case, and it was not the baby with the lowest oxygen saturation.

(ii) Carbon-dioxide tension (pCO<sub>2</sub>). Low, normal and high pCO<sub>2</sub> values were equally found. Values between 34 and 45 mm Hg were considered normal [7]. Sequence in Table II is arranged according to pCO<sub>2</sub> values.

(a) Three babies had low pCO<sub>2</sub> values. The level of standard bicar-

bonate was low and the base excess pronounced, indicative of metabolic acidosis presumably caused by hypoxia. Standard bicarbonate values between 21.3 and 24.8 mEq/litre and a base excess between -2.3 mEq/l and + 2.3 mEq/l were considered normal. Metabolic acidosis was present in all patients. This explains why the low  $pCO_2$  was not accompanied by respiratory alkalosis, while the blood pH reached the uppermost limit of normal in one case.

(b) A normal  $pCO_2$  was found in five babies. Low blood pH, low standard bicarbonate and high base excess, i.e. the signs of metabolic acidosis were present in these cases

also. A normal  $pCO_2$  associated with acidosis of this degree means that respiration is unable to adapt itself to the existing acidosis.

(c) A high  $pCO_2$  occurred in half of the patients, and it was this group which exhibited the highest mean value and the lowest individual value of blood pH (7.245 and 7.09, respectively). The fact that — with a single exception — standard bicarbonate and base excess were low admits of the conclusion that metabolic acidosis associated with and intensified by respiratory acidosis in this group.

As regards changes caused by a five-minute  $O_2$  inhalation, the material could be divided in three groups.

(a) Table III presents data of ten babies in whom an increased arterial pO<sub>2</sub> was accompanied by a decreased pCO<sub>2</sub>. Both the increase and the decrease were significant statistically ( $p < 0.1$  per cent). Arterial pH rose from 7.255 to 7.28. This readjustment of the blood gases means the near accomplishment of the desired therapeutic result, i.e. the relief of hypoxia by increasing pO<sub>2</sub> and O<sub>2</sub> saturation, the elimination of respiratory acidosis and the compensation of

metabolic acidosis by a reduction of the high pCO<sub>2</sub>.

(b) Table IV present values for four cases in which the increase in arterial pO<sub>2</sub> was accompanied by an increase in pCO<sub>2</sub>. The elevation of pO<sub>2</sub> was significant statistically ( $p < 0.1$  per cent), and it was considerable also in respect of the pCO<sub>2</sub> ( $p < 5.0$  per cent). Arterial pH decreased. The initial pCO<sub>2</sub> value was subnormal in two cases and did not exceed the normal level even after

its rise. This value was a *limine* above normal in another two cases, O<sub>2</sub> inhalation in this group elevated the CO<sub>2</sub> level instead of reducing it, evidently because breathing — which, so far, had been able to perform its function — deteriorated still further, thus upsetting the mechanism of CO<sub>2</sub> exchange. Arterial pCO<sub>2</sub> may reach dangerous heights in such cases.

(c) Table V presents a case in which both arterial pO<sub>2</sub> and pCO<sub>2</sub> decreased. This baby, becoming restless on inhaling O<sub>2</sub>, did not receive as much O<sub>2</sub> as would have sufficed to raise the arterial pO<sub>2</sub>, while increased breathing intensified by excitement, eliminated an additional volume of CO<sub>2</sub> from the lungs.

In none of the cases was the decrease in pO<sub>2</sub> accompanied by increase in pCO<sub>2</sub>. A phenomenon of this kind would not have been compatible with spastic bronchitis, since such changes in the blood gases point to a complete obstruction of the respiratory tract.

#### DISCUSSION

We have seen that the effort of the organism to compensate metabolic acidosis caused by hypoxia resulted

in a low arterial pCO<sub>2</sub> in not more than 20 per cent of the cases, while it failed to reduce pCO<sub>2</sub> in the majority. Inhalation of O<sub>2</sub> resulted in an elevation of pCO<sub>2</sub> in four cases, i.e. in nearly 25 per cent, a phenomenon that might cause some apprehension concerning the O<sub>2</sub> treatment of infantile bronchitis. REYNOLD [5] does not acknowledge the importance of this phenomenon, and suggests that a rise in pCO<sub>2</sub> need not interfere with O<sub>2</sub> administration.

It is known that the peripheral chemoreceptors for O<sub>2</sub> and CO<sub>2</sub> play an important part in the stimulation of the respiratory centre, especially in premature babies and infants [4, 9]. O<sub>2</sub> and CO<sub>2</sub> are presumably important factors in the maintenance of forced breathing in cases of spastic bronchitis; such breathing is of vital importance because it ensures that gas exchange without which no life is possible. It may happen that the improvement of hypoxia on O<sub>2</sub> inhalation deprives the organism of that important respiratory stimulus. Since, however, airway obstruction persists, the increase in pO<sub>2</sub> will be associated with an increase of pCO<sub>2</sub> because of the hypoventilation. The increased pCO<sub>2</sub> promotes breathing for some

time, but it will act in the opposite direction and paralyse above a certain limit the respiratory centre. It is, therefore, possible that in spastic bronchitis the inhalation of  $O_2$  relieves the hypoxia, cyanosis and restlessness, while increasing accumulation of  $CO_2$  causes sudden and fatal respiratory paralysis. This does not mean that  $O_2$  administration must be dispensed with, the less so as hypoxia, too, may be fatal. If only follows that, when  $O_2$  treatment is applied in diseases associated with airway obstruction, changes in arterial  $pCO_2$  should carefully be followed.

#### SUMMARY

Changes in the blood gases and in the acid-base balance, caused by a five-minute inhalation of  $O_2$ , have been studied in 15 infants suffering from spastic bronchitis. Grave hypoxia with low  $pO_2$  and low arterial saturation was observed in nearly all babies before the inhalation of  $O_2$ . Low standard bicarbonate and high base excess values, encountered in nearly all cases, pointed to metabolic

acidosis, presumably a consequence of hypoxia. The  $pCO_2$  was below normal in about 20 per cent of the cases and normal or above normal in the rest, a sign showing that metabolic acidosis was accompanied by respiratory acidosis. In cases with a low  $pCO_2$  the pH of arterial blood was around the lowest normal value since the patients were able to compensate metabolic acidosis by respiration. Disorders of ventilation impeded this compensation in the rest of the patient and their blood pH became correspondingly low.

$O_2$  inhalation yielded satisfactory results in 10 cases, as arterial  $pO_2$  increased and  $pCO_2$  decreased. The rise of  $pO_2$  was associated with a rise of  $pCO_2$  in four cases, presumably because stimulation of the respiratory centre and consequent ventilation, maintained during hypoxia via the peripheral chemoreceptors, were diminished by  $O_2$  treatment, so that the constriction of the respiratory tract promoted the accumulation of  $CO_2$ . Continuous recording of the arterial  $CO_2$  level in patients subjected to  $O_2$  treatment is, therefore, imperative.
